### THE THERAPEUTIC VALUE OF OXYGEN INHALATION, WITH EXHIBITION OF ANIMALS UNDER HIGH PRESSURE OF OXYGEN.[1]

BY W. GILMAN THOMPSON, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE NEW YORK UNIVERSITY MEDICAL COLLEGE; PHYSICIAN TO THE PRESBYTERIAN AND NEW YORK HOSPITALS.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY: The subject of my paper this evening is: "The Therapeutic Value of Oxygen Inhalation," with experimental demonstration of the effects upon animals of continued inhalation of oxygen under very high pressures.

With regard to the therapeutic use of oxygen, I present nothing especially new; but I have been impressed by the fact that this agent, which is by many considered invaluable, by other equally competent observers is rated as worthless, and by others, again, is employed from time to time in an indefinite way, with but little thought as to the real nature of its effects. For example, it is given for anæmia for five or ten minutes, two to three times a day, greatly diluted, and it is given pure for consecutive hours in dyspnœa arising from very diverse causes.

It is the object of my thesis to discuss briefly the physical and physiological problems associated with oxygen inhalation, and to suggest certain points for discussion which may enable us to formulate more definite views than at present prevail.

The experiments to be directly recounted are as yet incomplete, and the conclusions which they beget may possibly require modification in the light of additional trial.

The fundamental facts bearing upon the problem of absorption of oxygen gas are familiar. I will, therefore, merely sum them as concisely as possible.

1. The normal atmospheric pressure is (practically) 15 pounds to the square inch.

2. The gases, oxygen and nitrogen, exist in the atmosphere, each under a "partial pressure" by which the oxygen represents 3 pounds, and the nitrogen 12 pounds, corresponding to their normal admixture in the air in the proportion (in round numbers) of one part of oxygen to four of nitrogen. If oxygen be allowed to completely replace the nitrogen of the air, it, of course, exerts the entire pressure of 15 pounds.

The question arises, Does such an atmosphere, namely, 15 pounds to the square inch of pure oxygen, really cause more oxygen to be absorbed by the blood? In answer to this question, the following statements have long been accepted by physiologists as positively proven:

1. The hæmoglobin of the red blood-disks has a remarkable affinity for oxygen.

2. In addition to the oxygen, which forms a fixed part of its composition, hæmoglobin carries a varying quantity of "respiratory oxygen" in loose chemical combination, which is readily absorbed from the air in the lungs, and which is parted with in equal readiness in the systemic capillaries.

3. The blood, while passing through the lungs under normal conditions, subjected to a pressure of one atmosphere of air, becomes very nearly—fully $\frac{19}{20}$ — saturated with respiratory oxygen.

4. The plasma carries but very little oxygen—not over two per cent. by volume.

5. The atmospheric air, in saturating hæmoglobin with oxygen, forming oxy-hæmoglobin, loses (in round numbers) 5 parts of oxygen out of the 21 parts per 100 which it contains, returning, therefore, 16 parts of unused oxygen by exhalation. In breathing pure oxygen, will the hæmoglobin still appropriate but 5 parts of that gas, leaving 95 parts per 100 unused? It will; therefore, if more oxygen is taken into the blood when the oxygen exists under a total pressure of 15 pounds, it must enter the plasma, and not the hæmoglobin.

Reduced hæmoglobin absorbs oxygen a little quicker in pure oxygen gas than in air; but the difference is inconsiderable, and the quantity absorbed is ultimately the same in experiments outside of the body.

Can the blood plasma absorb more oxygen in an atmosphere of pure oxygen exerting 15 pounds of pressure? Let us for a moment admit that it may. Obviously, one of two results must occur: first, the additional oxygen may remain in the plasma so long as the tension of oxygen inhaled is maintained at the increased rate, producing no special effect, and it would be exhaled again as soon as the tension of the inhaled oxygen is lowered to the normal; in the same manner that nitrogen is known to be absorbed in small amount (two per cent.) by the plasma, to be eliminated again unaltered.

Or, secondly, the increased amount of oxygen absorbed might occasion greater oxidation in the tissues, with increased metabolism, represented by larger quantities of $CO_2$, $H_2O$, and other products.

Very careful experiments have been made to determine whether these waste materials are increased by continued inhalation of pure oxygen at 15 pounds of pressure, and it has been conclusively shown that they are not increased to any appreciable extent. Moreover, it has been proved that the blood plasma really absorbs but very little additional oxygen under any pressures which are compatible with maintenance of life. Bert. in his classical work upon "La Pression Barométrique," has shown that at 1 atmosphere the blood absorbs 20 volumes per cent. of oxygen; at 2 atmospheres it absorbs 0.9 volume per cent. additional; at 3 atmospheres, 0.7 volume per cent.; at 8 atmospheres only 0.1 volume per cent.; and the total additional oxygen absorbed under a pressure of 10 atmospheres amounts to only 3.4 volumes per. cent.

All experiments upon blood removed from the body unite in demonstrating that in pure oxygen, under one atmosphere of pressure, the blood takes up scarcely any more of the gas than it appropriates from common air. Quinquand found that in the dog arterial blood contained only 1 volume per cent. more oxygen after inhaling pure oxygen at a pressure of one atmosphere, and venous blood gained $2\frac{1}{2}$ volumes per cent. of oxygen.

Is it possible that the simple problems of absorption of oxygen by the blood, when shaken in a retort, are modified when the gas has to reach the plasma through the medium of the lungs? Let us consider the latter condition.

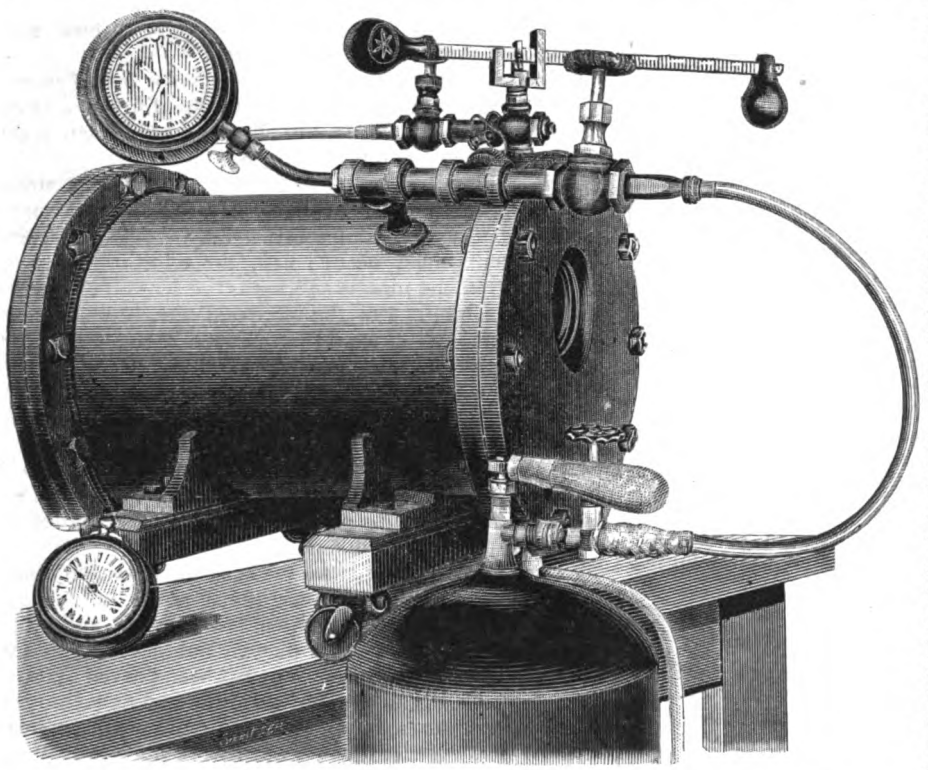
The amount of any gas absorbed by a liquid through a membrane depends upon: 1, the specific nature of the gas and of the liquid; 2, the temperature; 3, the density of the membrane; 4, the gas-pressure.

It is possible that slight variations in the composition of the plasma may influence to a small degree the amount of oxygen absorbed. The change in temperature of oxygen on entering the lungs, even under compression, is not sufficient to materially affect the rate of absorption. The density of the membranes, namely, the epithelium of the air-cells, is so

[1] Read before the New York Academy of Medicine, May 16, 1889.

especially the walls of the pulmonary capillaries, may conceivably vary with the amount of blood present, and influence the gas absorption.

In some of the older text-books of physiology the statement is made that animals cannot live in an atmosphere of pure oxygen, because it rapidly burns up their tissues as it burns a candle; *i.e.*, their greatly increased metabolism causes rapid tissue waste, convulsions, and death. This is a still prevalent popular fallacy. Later experimenters have claimed that the convulsions, etc., were due to retention of $CO_2$ and other waste products (possibly volatile ptomaïnes), which are reinhaled. Dr. Andrew H. Smith showed, by a series of most instructive and exhaustive experiments, made in 1869–70, that so long as the exhaled $CO_2$ and nitrogenous waste are removed, animals live for many hours in pure oxygen under ordinary atmospheric pressure, without any symptoms or appreciable change.



I have repeated many similar experiments, and demonstrated that the same is true with regard to inhalation of oxygen under pressures not exceeding 1½ or 2 atmospheres. Beyond this pressure the mechanical effects upon the circulation and the interference with proper gas diffusion in the lungs become manifest late or soon, according to the degree of pressure employed.

The only effects experienced by those in health who have inhaled oxygen freely are vague and inconstant, and many of these effects may be due to the gas not being absolutely pure. Some describe a sensation of freedom about the chest, as if respiration were easier, or they speak of a feeling of warmth beneath the sternum, or of coolness, slight vertigo, warm hands and feet. More blood flows to the surface of the body sometimes, and there may be slight formication. Some incline to drowsiness, others to increased muscular activity. There is often increased appetite and consequent gain in weight. The pulse may or may not be accelerated. The temperature is usually unaltered. Uric acid is said to be diminished (Kohlmann and Eckard). I have sometimes noticed an increase in the rate of breathing while inhaling pure oxygen, but this has always been due to voluntary suction effort on the part of the patient, and it can be easily avoided by giving proper instruction.

Several deep voluntary inspirations of oxygen produce condition known as apnœa, in which the breath can be for several seconds longer than usual without discomfort. An interesting fact has been demonstrated by Bert, that, under an air-pump, animals can withstand a greater reduction of pressure in an atmosphere of pure rarefied oxygen than in an atmosphere of rarefied air. Quinquand describes uniform reduction of the pulse in animals inhaling pure oxygen amounting to from 10 to 15 beats, and a corresponding reduction of 4 or 5 respirations, and ½–1° C. reduction in temperature. Bert found increased sugar in the blood of animals kept under increased oxygen pressure. From the foregoing summary of the physics of oxygen absorption it appears that, under given conditions of healthful circulation and respiration, but very little additional oxygen can be made to enter the blood by any degree of pressure short of that which mechanically interferes with those functions. In confirmation of this statement, and before considering the effect of oxygen upon abnormal circulation and respiration, I will cite a few of the experiments recently made with the apparatus here presented.

The apparatus, which was made for me by the Delamater Iron Works in this city, is of very simple construction. It consists of an iron locomotive cylinder with one removable head. A window of ½-inch plate-glass is inserted in either end of the cylinder, so that the animals can be constantly observed. A steam-gauge records the pressure of the gas, which is admitted through a valve connected by a strong tube with an ordinary oxygen cylinder, purchased from the oxygen manufacturer. The oxygen in these cylinders is sold under a pressure of 225 pounds or more, and as the cylinders are approximately the size of my own tank (36,700 c.c.), I readily get a pressure of 100 pounds by simply opening the valve. The tank has an exhaust valve for quickly releasing the pressure. It is painted white within, and furnished with an electric light. A wire grating is arranged to keep the animal off the floor and allow room for urine, and for materials used to absorb waste products. Food can be put in, and the animal may be left comfortable for any desired period. The exhalations may be tested at any time by collecting a little of the air from the exhaust valve. The removable head is so large that a good-sized dog can be put in through the opening. It is screwed on by many bolts, and leakage is prevented by rubber packing and red-lead. The apparatus is practically air-tight, for all the pressures at which I have used it. The character of the breathing, tracheal râles, cries, etc., can be very well auscultated through the iron wall of the tank and dense air within.

(Many interesting details of the following experiments are omitted for the sake of brevity.)

*Experiment* 1.—Two pigeons and a monkey were together placed in the tank and oxygen was added, 5 pounds at a time, at intervals of 5 minutes, until 30 pounds were reached, *i.e.*, 2 atmospheres of oxygen + 1 of air already present—three atmospheres in all. Up to this pressure no effect at all was produced except that the pigeons seemed drowsy, while the monkey was lively and playful. The monkey then showed moderate dyspnœa with mouth-breathing, and respiration rose from 35 to 70. The oxygen pressure was raised to 35 pounds, and in 5 minutes the monkey had a slight convulsion. The pigeons remained unaffected.

The pressure was gradually blown off, the convulsions

ceased, and after remaining 45 minutes in the tank the animals were released and appeared normal. The monkey's temperature had fallen 1¼° F. The temperature of one pigeon fell 4½° F.; that of the other 6° F. No evacuation of urine or fæces. Hæmoglobin normal.

This experiment merely shows what has been demonstrated by others, that animals can exist comfortably in an atmosphere composed of more than two-thirds oxygen, under moderately increased pressure, without any discernible alteration in their functions or demeanor, until the pressure exceeds three atmospheres.

*Experiment* 2.—A second monkey was kept in the tank for 1¼ hour under 11 pounds of additional oxygen pressure. No effect, except that he appeared sleepy and rather bored. On removal the rectal temperature had fallen 1½° F. As the tank air was blown off a pigeon was placed in a jar of it, and in 6 minutes it had convulsions, although a candle burned brightly in the same jar. A counter-test was made by placing another pigeon in fresh air in another jar of the same size. In the same time, 6 minutes, the second pigeon had no dyspnœa, yet a candle was extinguished at once in the jar.

The fact that the first pigeon had a convulsion in an atmosphere that relighted a paper, is probably due to poisoning from the monkey's nitrogeneous waste.

*Experiment* 3. — A guinea-pig, a dog, and an alligator were together placed in the tank, and oxygen was rapidly added, until in 15 minutes a total pressure of 5 atmospheres was reached. The dog then had a convulsion. The pressure was released slowly, and after 40 minutes it registered 20 pounds. The animals all seemed comfortable, so oxygen was added again up to 45 pounds, or 4 atmospheres in all. After a few minutes the valve was slowly opened and the animals were released, having remained 1½ hour in the tank. The pig and dog both died in 3 minutes in convulsions. Autopsies showed great pulmonary congestion in both animals, and over-distention of the right heart. The other viscera were exsanguinated. The venous blood was nearly black. The dog's temperature had fallen 9° F., and the pig's 14° F. The alligator's rose from 51½° (external air 66°) to 75° or 23¾° F. The alligator survived.

This experiment, with several others, shows that the higher animals are sooner affected by pressure than the lower. The monkey was asphyxiated before the pigeons, the dog before the guinea pig.

The remarkable fluctuation in temperature observed in nearly all these experiments is interesting, but I do not attribute it to the influence of oxygen. I have never noticed a rise of temperature in these experiments except in cold-blooded animals, and this fact alone argues against increased tissue oxidation.

In warm-blooded animals the normal temperature averages considerably higher than in man, and fluctuations of 6° or even 10° F., which are occasioned by trivial causes, may occur without any serious attending phenomena. I have often seen a dog's temperature fall 3° or 4° from simply inhaling ether. The heat-regulating mechanism of the lower animals is far less perfect than our own. They have a greater range of temperature in individual cases. In these experiments the fall of temperature noted is undoubtedly produced merely by the profound disturbance in the circulation and consequent increased heat-loss or diminished heat-production. Moreover, the rapid release of the pressure abstracts heat from the surface of the body. The fall of temperature is equally decided in atmospheres of compressed air and of compressed oxygen. It is greatest when the pressure has been very high, where it has been suddenly removed, and when convulsions and dyspnœa have been intense. I have often noticed a similar loss of temperature produced by asphyxiating an animal under an air-pump. Therefore this remarkable heat-loss is in nowise associated with an increase in oxygen absorbed.

*Experiment* 4.—A monkey was kept in the tank for 2¼ hours, under a pressure which was gradually increased up to 45 pounds of oxygen, and then slowly diminished. The animal during all this time played about, and seemed perfectly normal. When the pressure reached zero it was suddenly raised again in 8 minutes to 51 pounds of oxygen, nearly 4½ atmospheres in all. He was kept at nearly this pressure for 45 minutes more, without appreciable effect of any kind. Just before removal, after spending 3½ hours in the tank, the animal had a slight convulsion. The rectal temperature fell 1½°.

*Experiment* 5.—Is a repetition of the preceding experiment. A monkey and pigeon were kept for over two hours in the tank under a pressure of oxygen which registered 30 pounds during most of that time. Very slight dyspnœa occurred toward the end, but no other symptoms resulted. The monkey's temperature fell 4.2°, the pigeon's only 1° F.

*Experiment* 6.—A cat was placed in the tank, and oxygen pressure was rapidly added until, at the end of an hour, it registered 90 pounds—in all 7 atmospheres. No convulsions occurred until 70 pounds of pressure was reached. After 1½ hour in all the animal was removed, and it soon died from pulmonary congestion and dilatation of the right heart. Some emphysema was found in the thinner portions of the lungs Bert states, as a result of his experiments, that at 3½ atmospheres of oxygen, animals die from asphyxia and convulsions. In this experiment, twice that pressure was borne for some time, although it ultimately proved fatal.

*Experiment* 7.—Three pigeons were kept for 1½ hour under a pressure of 40 pounds of oxygen, nearly 4 atmospheres in all. One of them alone had convulsions, and on removal it remained for some days with the muscles in a curious condition of rigidity and contracture, and all attempts at moving it threw it into violent convulsions. The bird lay on its back for four days, with neck and legs strongly flexed. The animal had had its cerebellum removed some weeks before, and I think the peculiar symptoms were due to the pressure affecting the surface of the brain unduly through the opening in the skull, rather than to any influence of the oxygen. The two other pigeons survived, and were normal.

*Experiment* 8.—A dog was kept for an hour at a pressure of 4 atmospheres, composed of three-fourths oxygen. There were a few convulsions, but the dog recovered. The rectal temperature fell 5.4° F.

*Experiment* 9.—A cat and dog were kept alive for an hour under an additional atmosphere of oxygen in a confined space, where the ordinary air would have been fatal to either animal alone in less than half that time.

*Experiment* 10.—A similar experiment was repeated, using compressed air instead of oxygen, with a like good result. Having determined the effect of high pressures of oxygen, I next tried to learn to what extent the convulsions which are common above 4 atmospheres, are caused by the pressure alone, or to what extent they might be due to some specific action of oxygen. In all the experiments thus far described, the convulsions were immediately relieved by blowing off 5 or 10 pounds of pressure. It is also noticeable that, while the pressure was being either increased or diminished, the animals evinced a certain amount of restlessness, which was usually greater when the pressure was falling, and which promptly subsided. In the following experiments the animals were subjected to exactly the same conditions upon successive days, with the exception that compressed air was used on one day, and oxygen on the next. The pressure was added or released at the same rate in each case, and the exhaled $CO_2$ was removed by a solution of KOH.

*Experiments* 11 *and* 12.—A dog weighing 22½ pounds, was subjected to rapidly increasing air pressures. A total pressure of 8 atmospheres was reached (inside of 26 minutes) before the animal had a convulsion, or even appeared discomforted. When oxygen was given the next day, at the same rate, convulsions occurred when the total pressure had reached 5 atmospheres, and when 6⅓ atmospheres were reached the convulsions became so

violent as to shake the heavy tank and threaten immediate death. It was with difficulty that he was rescued by releasing the pressure, and whereas on coming out of 8 atmospheres of compressed air the dog appeared normal, on coming out of 6½ atmospheres of oxygen he had tremors, incoördination, salivation, staring eyes, and jerky dyspnœic respiration. There were no râles in the chest. Ether was given to control the convulsions which persisted after his liberation, and he survived.

*Experiment* 13.—A further test was made the next day by allowing this dog to remain in the closed tank, breathing common air under 15 pounds pressure, until he became decidedly asphyxiated in 27 minutes, with mouth breathing and respiration, 120. Ten pounds of oxygen pressure were added, and the respiration fell to 38, with great relief of the dyspnœa. The oxygen pressure was finally raised to 45 pounds, when convulsions occurred.

*Experiments* 14 *and* 15.—A cat and dog were together placed in the tank and allowed to remain until, after 20 minutes, both animals were decidedly asphyxiated. When both animals were on the verge of convulsions, the dog's respiration being 120 and the cat's 80, 5 pounds of oxygen pressure was added, with instant relief; the dog's respiration fell to 40 and the cat's to 60. When the dyspnœa again returned after an interval, it was always relieved by adding a little oxygen until 30 pounds pressure had been reached. After 50 minutes the animals were released in good condition. The exhaled air, collected at intervals, contained a very large percentage of $CO_2$, yet a candle burned brightly in it. The next day the same animals were replaced in the tank and 22 pounds of oxygen pressure were added at once, which they bore for 45 minutes, with but slight dyspnœa toward the end.

*Experiments* 17 *and* 18.—A large cat was placed under a pressure of 55 pounds of oxygen or 4⅜ atmospheres in all, and in 2 minutes severe convulsions resulted. The next day the same animal was kept for 35 minutes under the same pressure of atmospheric air without any ill effects at all.

The day following, the animal was left in the tank for 20 minutes, when it showed intense dyspnœa (the cat's body filled $\frac{1}{10}$ of the capacity of the tank); 10 pounds of oxygen pressure were then added with immediate relief, which lasted for one hour. At the end of this time the oxygen pressure was increased to 30 pounds, and the cat remained comfortable for 3¾ hours in all. On removal a convulsion occurred, but the animal was restored by chloroform. KOH was used to absorb the $CO_2$. The rectal temperature fell 5½° F. during the experiment.

All of the experiments thus far reported were made with perfectly healthy animals. They prove that: 1. When the breathing is normal, oxygen and atmospheric air do not differ materially in effect up to about two atmospheres of pressure. 2. Both oxygen and air under pressures between ½ and 2 atmospheres relieve the dyspnœa produced by inhaling vitiated air, and oxygen has a distinctly greater effect in this regard than air. 3. The effect seems to be exerted through the respiratory centre, diminishing the rate of breathing, and improving the rhythm of the respiration.

4. Above 2 or 3 atmospheres a much greater pressure of air can be borne than of oxygen without inducing convulsions.

The cause of the convulsions is still undecided.

The cause of the ordinary normal respiratory impulses is believed, by the great majority of experimenters at the present time, to be the lack of oxygen in the blood conveyed to the respiratory centre in the medulla. Others, however, believe that the presence of excess of $CO_2$ in the blood is an equally potent factor; and there are a few physiologists who claim that the lack of oxygen excites inspiration, and that the presence of excessive $CO_2$ may excite forced expiration.

Convulsions are produced by suddenly withholding oxygen, and convulsions of a somewhat different type may be produced by inhaling a large percentage of $CO_2$. It is possible that they may be also produced by nitrogenous waste matters (probably volatile ptomaïnes?), which are either re-inhaled, or which cannot be exhaled. Whichever theory we adopt, the fact remains that the convulsions are precipitated when the pressure of the inhaled atmosphere reaches a certain maximum. I submit the following theory regarding these convulsions: That they are due to the physical law that "the diffusion constant of two gases is inversely as the pressure," and, therefore, the higher the pressure the less the rate of diffusion. In normal breathing the air in the upper part of the lungs only is exchanged mechanically, as we know. The air of the more deeply seated air-vesicles, which contains an excess of $CO_2$, is changed by diffusion at a definite rate for ordinary atmospheric pressure. If the pressure of the inhaled atmosphere, be it oxygen or common air, is greatly increased, it is more difficult, and it requires more time for the $CO_2$ to diffuse from the blood into the air-vesicles, and from the air-vesicles into the tidal air in the wider portions of the air-passages. As a result, $CO_2$ tends to accumulate in the blood, and, further, by its retarded diffusion from the residual air in the vesicles, it tends to keep back the oxygen of the tidal air from closer approach to the capillaries. Hence the blood is prevented from taking up sufficient oxygen, and at the same time its $CO_2$ and volatile nitrogenous waste matter accumulate, and convulsions result. The fact that increased oxygen pressure causes convulsions sooner than increased air pressure may possibly be due to the greater difficulty that $CO_2$ experiences in diffusing into pure oxygen highly compressed, as compared with common air; but this is at present purely hypothetical. Another very important consideration is the fact that, with greatly increased pressure the solubility of $CO_2$ in the blood is much increased, and it therefore tends to diffuse out less readily into the air-cells.

Pure oxygen under *slightly* increased pressure is beneficial, because it mixes readily enough with the $CO_2$ present in the lungs, and *a very little* more of it may be absorbed by the plasma. But under greatly increased pressure diffusion becomes too slow and difficult, and convulsions ensue.

The next problem is the discussion of the influence, upon abnormal respiration, of oxygen, inhaled under increased pressure. For the present purpose, without going deeply into the manifold exciting causes of dyspnœa, we may classify its principal varieties as follows:

I. Dyspnœa due to abnormal conditions of the air, especially to diminished oxygen supply from obstruction to the entrance of air, to increased $CO_2$ or nitrogenous waste, or to other poisonous gases.

II. Dyspnœa due to abnormal conditions of the blood, either diminished number of red disks, or diminished oxygen carrying power of the red disks—*i.e.*, diminished hæmoglobin.

III. Dyspnœa due to obstructed circulation, arising from a feeble heart, pulmonary congestion, etc., which retard the blood-current.

IV. Dyspnœa due to diminished surface of aëration for the blood, from compression of the lung by fluid, from consolidation, or other cause—as feeble expansion of the chest.

V. Dyspnœa of purely neurotic character, with normal lungs.

Regarding the latter, it may be said that there seems to be a general "respiratory sense," corresponding to the general sense of hunger, thirst, etc. We mentally refer dyspnœa to the chest, as we mentally refer thirst to the throat; yet in cases of gastric fistula, thirst is relieved by injecting water into the stomach. Thirst may also be relieved by immersing the body in water.

It is a matter of common observation, to see certain cases of pneumonia or of phthisis in which the patient, while perfectly conscious, feels no distress in breathing, yet the rhythm and rate of respiration are wholly abnormal. On the other hand, there may be decided subjective dyspnœa without discoverable lesion in the respiratory

system, such as occurs in hysteria, and as a premonition of uræmia, etc.

I am at present engaged upon a series of new experiments by which some of these varieties of dyspnœa are artificially induced, and then the effect of inhalation under pressure of oxygen is studied.

A few of these experiments I will report:

*Experiments* 19 *and* 20.—In a cat with both vagi cut, there was no appreciable dyspnœa so long as the animal remained quiet and had plenty of air. The cat was shut in the tank, breathing confined air, uncompressed, until intense dyspnœa resulted of the well-known cut-vagus type. Inspiration became very deep and prolonged, the nares and mouth were wide open, every accessory respiratory muscle was called into action, and an exaggerated pause occurred between the end of inspiration and beginning of expiration, the latter being sudden and forcible. In addition there were tremors of the head and legs; 7 pounds of oxygen pressure were then added, with instant relief of all the symptoms. The cat was removed after fifteen minutes, and allowed to rest until the next day, when it was still alive with quiet respiration. The animal was then urged to walk a few steps until intense dyspnœa occurred as before. On being placed in the tank in this condition, compressed air was added under the same pressure as the oxygen used on the previous day. Instead of producing relief the dyspnœa was augmented, and when the pressure was increased to three atmospheres the dyspnœa became most intense. There were loud tracheal râles audible through the wall of the tank, which transmits respiratory sounds with remarkable clearness. Restlessness and weakness became extreme. On releasing the animal it was restored to its previous condition of comfort. In these experiments the pressure effects were very decided.

*Experiment* 21.—It took forty minutes for the same animal to acquire marked dyspnœa, with both vagi cut, in confined air at one atmosphere, whereas two atmospheres of air produced immediate severe dyspnœa. The interesting feature of these experiments is that the dyspnœa which occurred in an exaggerated form after section of both vagi and poisoning by confined air, was relieved by adding seven pounds pressure of oxygen to the already foul air.

*Experiment* 22.—A young but large dog, with a cannula ½-inch in diameter inserted in right pleural cavity. When the cannula was closed with a cork, respiration was normal; when it was open there was great dyspnœa, and respiration was increased to 66 and shallow. The dog was placed in the tank with the cannula open, and 15 pounds pressure of oxygen were added. In twenty minutes respiration fell from 66 to 32, and became deep and very labored. The oxygen was blown off and the respiration rose to 47. Then 40 pounds pressure of common air were added. The animal again became very uneasy and the respiration slower and deeper. In fifteen minutes more he was liberated, and the cork was replaced.

This experiment demonstrates that, when an animal is deprived of half the normal breathing-space by collapse of one lung produced by a free opening in the pleura, both compressed oxygen and compressed air reduce the frequency of respiration, but add greatly to the distress of the animal from the mechanical effects of the pressure. If there was any specific difference between the oxygen and common air in this case, it was obscured by the evil mechanical effects of the increased pressure.

*Experiment* 23.—In another experiment I produced extreme dyspnœa from local pulmonary congestion from injection of $AgNO_3$ solution into the lung tissue. The animal (a cat) was placed in the tank when the respiration was 150 and very shallow; there was great prostration, the animal being scarcely able to stand. Ten pounds of oxygen pressure were added, and in three minutes respiration was slowed to 80 and became much fuller, and the animal seemed greatly relieved and stronger. On increasing the oxygen pressure to 20 pounds the respiration fell to 64, the cat stood up, licked her paws, and moved about in a natural manner. After an hour under this pressure the cat was liberated, and she became immediately worse. The respiration increased, and the cat again became so feeble as to constantly lie down. In this case of acute pulmonary congestion the inhalation of oxygen under pressure gave remarkable relief to the dyspnœa and general distress. Autopsy showed only one lobe to be congested on the side of the injection.

*Experiment* 24.—Dog, weight 16½ pounds. I injected 550 c.c. of water into a dog's right pleural cavity to compress the right lung and diminish the space for aëration of the blood. Respiration became very deep and labored, and while at rest the rate was 35. While exercising, respiration became 100 and shallower. The animal was placed in the tank, and 10 pounds were added of a mixture of 4. oxygen + 1 ($N_2O$). In three minutes respiration fell from 60 to 48, and the dog seemed much relieved and very drowsy. After 15 minutes the pressure was gradually increased to 45 pounds, when a violent convulsion occurred in four minutes. This was controlled by releasing the pressure slowly. After remaining one hour in the tank, the animal was removed. The temperature had fallen 4¼° F.

In this experiment, where the area for aërating the blood was diminished by one half, the respiration became much more natural on inhaling a mixture of 4. oxygen + 1 ($N_2O$) under pressure. No different effect was noticed in using this mixture from that obtained by pure oxygen.

*Experiment* 25.—A puppy weighing 14½ pounds was bled to the extent of 2½ ounces. Respiration became very irregular, and the animal appeared very weak. He was given the same mixture of 4. (O) + 1 ($N_2O$) under various pressures. At pressures under 10 pounds he was much relieved, but under three atmospheres the dyspnœa was greatly increased, and he became too feeble to stand.

*Experiments* 26 and 27.—A dog weighing 16¾ pounds was bled to the extent of 10 ounces. The resulting dyspnœa was relieved by adding 4 pounds of pressure of the mixture used in the previous experiments. Subsequently the dyspnœa returned, and being again placed in the tank under 10 pounds of oxygen pressure added to the air already present, his condition improved in a marked degree. But when 30 pounds of oxygen pressure were added, the dyspnœa became intense. It was again relieved by reducing the pressure.

These experiments have not been performed with high pressures because we can make any clinical use of such pressures. but in order to find the limits of the maximum effect of oxygen, as an aid to inferring the clinical results which are possible under one atmosphere of pure oxygen, *i.e.*, in which the oxygen tension is increased to 15 pounds. The experiments, although as yet incomplete, certainly demonstrate that oxygen under moderately increased tension does aid certain types of dyspnœa.

We now come to the second division of my subject, the Therapeutic Value of Oxygen Inhalation.

It is not very feasible to give oxygen to man under pressures above that of the atmosphere. My own experience in this regard is confined to the use of compressed air in a few severe cases of spasmodic asthma, which were greatly improved, I think, rather by the general air-pressure, than by the slight increase in oxygen tension produced by an additional atmosphere.

Dr. Valenzuela, in a paper read before the Royal Academy of Medicine of Madrid, two years ago, reports the use of oxygen inhaled under 7 times the ordinary oxygen tension of the air (*i.e.*, 1½ atmosphere of pure oxygen). Several cases of pneumonia in man were greatly benefited. At the end of an hour in one case the temperature fell 1.7° C. He also speaks of reducing the temperature of rabbits having septicæmia, by inhalation of oxygen under increased tension. For reasons given earlier in this paper, I believe that the reduction of temperature was due to pressure effects, and that it would have occurred equally had compressed air been used instead of oxygen.

The inhalation of oxygen is no new remedy. Its therapeutic use was suggested by its discoverer, Priestley, in 1774. But it has suffered much from the extolment of quacks, who take advantage of the popular knowledge that without oxygen there is no life, and the belief that, consequently, the more oxygen is given, the more vigor results, and that ozone is a public boon even beyond oxygen in power. Whereas, it is a physiological impossibility to take ozone into the blood through the lungs, and even were it possible, its presence there is incompatible with the continuance of the circulation (Oertel).

The legitimate clinical use of oxygen is, however, constantly advancing, not after the manner of so many new remedies that spread throughout the country, offering fame to all who first report their trial to-day, and which pass into oblivion to-morrow; but the advance is steady and convincing.

Until recently, oxygen could only be obtained from illuminating companies, and those who have given it trial in impure forms, and without system, have generally misjudged it. To-day it is prepared by many manufacturers, exclusively for medical use, with guarantee of its purity, and many of our hospitals have oxygen generators of their own.

Oxygen is employed therapeutically, 1, as a curative measure in diseases of the blood, circulation and respiration; and, 2, as a palliative measure in extreme subjective and objective dyspnœa.

The therapeutic use of oxygen is now very prevalent in the United States, and in Continental Europe. Two or three hundred thousand gallons are inhaled yearly in this city alone. During the cholera epidemics of Toulon and Marseilles, in 1886, it proved a most useful adjunct to other treatment. It is employed with success in many cases of opium narcosis, coal-gas asphyxia, chloroform poisoning, etc.

Decided success is claimed for its use in anæmia, chlorosis, leukæmia, slow convalescence, and in wasting diseases.

Hundreds of cases of dyspnœa and cyanosis complicating pulmonary diseases, have been reported in the journals of the past few years, as benefited by oxygen inhalation.

In 1888 it was ordered in Paris that oxygen be kept in readiness at each of the 16 pavilions erected on the banks of the Seine for the resuscitation of the drowned (*Lancet*, June 16, 1888, p. 1273), and it was further advised to keep it at all the police and fire stations. The literature of the therapeutic use of oxygen shows decided improvement in the intelligence and care with which it is given, besides affording such convincing evidence of its value in certain classes of disease, that no consideration of expense or trouble should weigh against it.

Adopting the previous classification of dyspnœa, I will refer to a few illustrative cases within my own experience.

I. *Oxygen in anæmia, chlorosis, etc.*—Oxygen is given for these affections often in a greatly diluted form, for 5 or 10 minutes, two or three times a day. If those cases be excluded which will recover anyway, and those which are simultaneously under other treatment, there is little evidence of any specific advantage of oxygen over good fresh air. In cases of this kind in which I have used oxygen, I have never employed it alone, but I have failed to note any benefit from it as an adjunct to iron and other remedies. It does not seem quite rational to suppose that enough oxygen can enter the system in this way, in so brief a time, to produce anything more than a momentary effect. Little or no additional oxygen enters the plasma under these conditions (of dilution, etc.), and the red corpuscles which are at fault have, in the ordinary air, more oxygen than they can appropriate. Besides, at least 10 inspirations are required to completely change the air in the lungs.

II. *Blood-poisoning.*—In diseases in which blood-poisoning of some kind was the occasion for the use of oxygen, I have uniformly failed to find any improvement in the condition of cyanosis, although I have watched for it with greatest care; but I have frequently seen the subjective dyspnœa relieved.

To illustrate. Two years ago, I treated a case of malignant diphtheria in which great prostration early occurred, with very rapid respiration (50), marked subjective dyspnœa and cyanosis. There was not enough membrane to cause any obstruction, and the lungs at the time were perfectly clear and well filled with each inspiration. There was no time to examine the blood, but it seemed to be a case in which the blood became suddenly overwhelmed with the diphtheritic poison, and either the red disks themselves, or their hæmoglobin, was destroyed. Oxygen was vigorously administered for several hours, without the slightest improvement in cyanosis or rate of respiration, although the patient, an intelligent adult, said he felt greatly relieved by the gas. Death soon followed from pulmonary œdema and heart-failure.

Last March, a robust adult entered the Presbyterian Hospital, as a case of illuminating-gas poisoning. On admission he was unconscious, and he remained so. His lungs were clear at first. Later, he developed pneumonia, from which he died on the third day. During the entire time his respiration continued at 72. Oxygen was freely given, almost continuously. It produced no effect whatever upon either the rate of breathing or the cyanosis, which occurred during several attacks of pulmonary œdema. Cupping the chest, and venesection to relieve the right heart, produced decided temporary improvement where oxygen completely failed. In these cases, as is well known, carbon-monoxide forms a compound with hæmoglobin which permanently replaces oxygen in the red disks; and in the instance cited, oxygen inhaled nearly pure was evidently not appropriated by the plasma in sufficient quantity to be of benefit.

III. *Affections of the circulation.*—In cardiac diseases, or in failure of the heart to maintain the pulmonary circulation at its normal velocity, oxygen is reported to be of considerable value. My own experience with it in cases of this class has not been so encouraging. For example, in a recent case of malignant endocarditis, with extensive valvular disease and dilatation, I found oxygen of no avail in relieving the dyspnœa, either before or after there were any physical signs of obstruction to the entrance of air to the lungs. When the circulation is feeble, and the blood-current through the lungs is impaired, the blood, while in the lesser or pulmonary circulation, has all the more time to appropriate oxygen and be relieved of $CO_2$; but the blood in the greater or systemic circulation reaches the lungs less promptly, and it accumulates more $CO_2$. It seems doubtful whether inhalation of oxygen in this condition can be of much avail.

IV. *Diminished surface for aëration.*—In pneumonia, with very rapid respiration, dyspnœa, and cyanosis, I have often found oxygen to give very great relief. It is even possible for the dyspnœa to be decidedly relieved, while the cyanosis disappears in a few seconds, and the rate of respiration becomes slower, and its character improves. The same is true of capillary bronchitis and of asthma, especially when accompanied by extensive bronchial secretion. Where the thorax is poorly expanded from enfeeblement of the respiratory muscles, thoracic pain, or obstruction to the air-passages, etc., it may be impossible to inflate the lungs normally, or to have as complete an interchange of gases within them as should take place.

Under these conditions increase in the amount of oxygen present in the inhaled air ought to allow a larger proportion of oxygen to reach the deeper air-cells in a given time.

V. *Neurotic dyspnœa.*—Oxygen gives decided relief to certain forms of neurotic dyspnœa, *i.e.*, dyspnœa occurring where the lungs are perfectly normal, but from some cause the respiratory sense suffers greatly. I have found it very beneficial in uræmic dyspnœa. In one such case with normal lungs, the most pronounced I have ever witnessed, very intense dyspnœa lasted for three days, and during this time oxygen was almost continuously used day and night. After inhalation for fifteen or twenty minutes, the respira-

tion became slower and more tranquil, the cyanosis (which occurred later on with pulmonary œdema) was slightly improved, and the patient was greatly eased. The dyspnœa soon returned if oxygen was discontinued, and improved when it was resumed. In cases of this nature, which so frequently occur, I have come to regard oxygen as an invaluable therapeutic agent, not for any curative effect—for the condition may be hopeless from the start—but as a prompt and easy aid to one of the worst forms of suffering—the continual sense of impending suffocation. It is possible that in some cases the benefit is psychic, but it does occur.

Much has yet to be decided regarding the effects of oxygen inhalation. We should have more careful experiments to determine whether the exhalation of nitrogenous waste (volatile ptomaïnes?) is increased by oxygen inhalation, and to determine whether more oxygen is conveyed to the blood by diluting it with some still more diffusible respirable gas, or by administering it pure. Experiments of this nature, combined with careful study of the body temperature and pressure effects, will, no doubt, throw more light upon the relation of oxidation processes to fever, etc. In conclusion, the following summary of the therapeutic value of oxygen inhalation is offered:

Oxygen is of value—

1. In neurotic dyspnœa, for the relief of the distressing subjective symptoms.

2. Where there is diminished surface for aëration of the blood, oxygen improves the cyanosis, lowers the rate of breathing, and relieves the subjective dyspnœa.

3. Oxygen is of value where there is diminished inflation of the lungs from many causes.

4. It is especially beneficial in the dyspnœas of chronic Bright's disease and uræmia, pneumonia, capillary bronchitis, asthma, and catarrhal bronchitis, and sometimes in pulmonary congestion, and the early stage of œdema.

5. Great care should be taken to secure chemically pure oxygen.

VI. Oxygen may be given freely and abundantly in cases of emergency, without fear of any injurious consequences. Ordinarly it is sufficient to give it pure by one nostril, while the other inhales atmospheric air; but it is often best to give it for a few moments by the mouth or both nostrils, without admixture of air.

It is impossible to separate completely the causes of dyspnœa, which may often exist in combination, but in order to focus somewhat the discussion invited, Mr. President, I would suggest, that it would be interesting to hear the views of those present regarding the value of oxygen inhalation:

1st. In general diseases of defective nutrition, without regard to dyspnœa.

2d. In dyspnœa due to altered condition of the nerves, or of the circulation, altered composition of the blood (poisons, etc.), diminished surface for aëration, or feeble expansion of the lungs.

In performing my experiments I have received valuable aid from Dr. John C. Cardwell, Assistant to the Physiological Laboratory at the New York University Medical College, as well as from several students of the College.

## ALCOHOLIC TRANCE IN CRIMINAL CASES.[1]

BY T. D. CROTHERS, M.D.,

SUPERINTENDENT WALNUT LODGE, EDITOR "JOURNAL OF INEBRIETY," ETC., HARTFORD, CONN.

THE frequent statement of prisoners in court, that they did not remember anything about the crime they are accused of, appears from scientific study to be a psychological fact. How far this is true in all cases has not been determined, but there can be no question that crime is often committed without a conscious knowledge or memory of the act at the time.

It is well known to students of mental science that in certain unknown brain states memory is palsied, and fails to note the events of life and surroundings. Like the somnambulist, the person may seem to realize his surroundings and be conscious of his acts, and later be unable to recall anything that has happened. These blanks of memory occur in many disordered states of the brain and body, but are usually of such short duration as not to attract attention. Sometimes events that occur in this state may be recalled afterward, but usually they are total blanks. The most marked blanks of memory have been noted in cases of epilepsy and inebriety. When they occur in the latter they are called alcoholic trances, and are always associated with excessive use of spirits. Such cases are noted in persons who use spirits continuously, and who go about acting and talking sanely although giving some evidence of brain failure, yet seem to realize their condition and surroundings. Some time after, they wake up and deny all recollection of acts or events for a certain period in the past. This period to them begins at a certain point and ends hours or days after, the interval of which is a total blank, like that of unconscious sleep. Memory and certain brain functions are suspended at this time, while the other brain activities go on as usual.

In all probability the continued paralysis from alcohol not only lowers the nutrition and functional activities of the brain, but produces a local palsy, followed by a temporary failure of consciousness and memory, which after a time passes away.

When a criminal claims to have had no memory or recollection of the crime for which he is accused, if his statement is true, one of two conditions is probably present, either epilepsy or alcoholism. Such a trance state might exist and the person be free from epilepsy and alcoholism, but from our present knowledge of this condition it would be difficult to determine this fact. If epilepsy can be traced in the history of the case, the trance state has a pathological basis for its presence. If the prisoner is an inebriate, the same favoring conditions are present. If

[1] Read before the International Medico-legal Congress, at New York City, June 5, 1889.

the prisoner has been insane, and suffered from sun- or heat-stroke, and the use of spirits are the symptoms of brain degeneration, the trance state may occur at any time.

The fact of the actual existence of the trance state is a matter for study, to be determined from a history of the person and his conduct; a grouping of evidence that the person cannot simulate or falsify; evidence that turns not on any one fact, but on an assemblage of facts that point to the same conclusion.

The following cases are given to illustrate some of these facts, which support the assertion of no memory of the act by the prisoner in court:

The first case is that of A——, who was repeatedly arrested for horse-stealing, and always claimed to be unconscious of the act. This defence was regarded with ridicule by the court and jury, and more severe sentences were imposed, until, finally, he died in prison. The evidence offered in different trials was, that his father was weak-minded and died of consumption, and his mother was insane for many years, and died in an asylum. His early life was one of hardship, irregular living, and no training. At sixteen he entered the army, and suffered from exposure, disease, and sunstroke, and began to drink spirits to excess at this time. At twenty he was employed as a hack-driver, and ten years later became owner of a livery stable. He drank to excess at intervals, yet during this time attended to business, acting sanely, and apparently conscious of all his acts, but often complained he could not recollect what he had done while drinking. When about thirty-four years of age he would, while drinking, drive strange horses to his stable, and claim that he had bought them. The next day he had no recollection of these events, and made efforts to find the owners of these horses and return them. It appeared that while under the influence of spirits the sight of a good horse hitched up by the roadside alone, created an intense desire to possess and drive it. If driving his own horse, he would stop and place it in a stable, then go and take the new horse, and after a short drive put it up in his own stable, then go and get his own horse. The next day all this would be a blank, which he could never recall. On several occasions he displayed reasoning cunning, in not taking a horse when the owners or drivers were in sight. This desire to possess the horse seemed under control, but when no one was in sight all caution left him, and he displayed great boldness in driving about in the most public way. If the owner should appear and demand his property he would give it up in a confused, abstract way. No scolding or severe language made any impression on him. Often, if the horse seemed weary, he would place it in the nearest stable, with strict orders to give it special care. On one occasion he joined in a search of a stolen horse, and found it in a stable where he had placed it many days before. Of this he had no recollection. In another instance he sold a horse which he had taken, but did not take any money, making a condition that the buyer should return the horse if he did not like it. His horse-stealing was all of this general character. No motive was apparent, or effort at concealment, and on recovering from his alcoholic excess he made every effort to restore the property, expressing great regrets, and paying freely for all losses. The facts of these events fully sustained his assertion of unconsciousness, yet his apparent sanity was made the standard of his mental condition. The facts of his heredity, drinking, crime, and conduct all sustained his assertion of unconsciousness of these events. This was an alcoholic trance state, with kleptomaniac impulses.

The next case, that of B——, was executed for the murder of his wife. He asserted positively that he had no memory or consciousness of the act, or any event before or after. The evidence indicated that he was an inebriate of ten years' duration, dating from a sunstroke. He drank periodically, for a week or ten days at a time, and during this period was intensely excitable and active. He seemed always sane and conscious of his acts and surroundings, although intensely suspicious, exacting, and very irritable to all his associates. When sober he was kind, generous, and confiding, and never angry or irritable. He denied all memory of his acts during this period. While his temper, emotions, and conduct were greatly changed during this time, his intellect seemed more acute and sensitive to all his acts and surroundings. His business was conducted with his usual skill, but he seemed unable to carry out any oral promises, claiming he could not recollect them. His business associates always put all bargains and agreements in writing when he was drinking, for the reason he denied them when sober. But when not drinking, his word and promise was always literally carried out. He broke up the furniture of his parlor when in this state, and injured a trusted friend, and in many ways showed violence from no cause or reason, and afterward claimed no memory of it. After these attacks were over he expressed great alarm, and sought in every way to repair the injury. Finally he struck his wife with a chair and killed her, and awoke the next day in jail, and manifested the most profound sorrow. While he disclaimed all knowledge of the crime, he was anxious to die and welcomed his execution. This case was a periodical inebriate with maniacal and homicidal tendencies. His changed conduct, and unreasoning, motiveless acts, pointed to a condition of trance. His assertion of no memory was sustained by his conduct after, and efforts to find out what he had done and repair the injury.

The third case, that of C——, was a man of wealth and character who forged a large note, drew the money, and went to a distant city on a visit. He was tried and sentenced to State prison. The defence was no memory or consciousness of the act by reason of excessive use of alcohol. This was treated with ridicule. Although he had drank to excess at the time of, and before, the crime, he seemed rational and acted in no way as if he did not understand what he was doing. Both his parents were neurotics, and he began to drink in early life, and for years was a moderate drinker. He was a successful manufacturer, and only drank to excess at times for the past five years. He complained of no memory during these drink paroxysms, and questioned business transactions and bargains he made at this time. On one occasion he went to New York and made foolish purchases which he did not recall. On several occasions he discharged valuable workmen, and when he became sober took them back, unable to account for such acts. These and other very strange acts continued to increase with every drink excess. At such times he was reticent, and seemed to be sensible and conscious, and did these strange acts in a sudden, impulsive way. The forged note was offered boldly, and no effort was made to conceal his presence or destination. When arrested he was alarmed, and could not believe that he had done so foolish an act. This was a clear case of alcoholic trance, in which all the facts sustained his assertion of no conscious memory of the crime. In these three cases the correctness of the prisoners' assertions of no memory was verified by all the facts and circumstances of the crime. The mere statement of a person accused of crime, that he had no memory of the act, should lead to a careful examination and be only accepted as a fact when it is supported by other evidence.

The following case illustrates the difficulty of supporting a prisoner's statement of no memory when it is used for purposes of deception:

An inebriate, case D——, killed a man in a fight, and was sentenced to prison for life. He claimed no memory or recollection of the act. I found that when drinking he seemed conscious of all his surroundings, and was always anxious to conceal his real condition, and if anything had happened while in this state he was very active to repair and hush it up. He was at times quite delirious when under the influence of spirits, but would stop at once if anyone came along that he respected. He would, after

acting wildly, seem to grow sober at once, and do everything to restore the disorder he had created. The crime was an accident, and at once he attempted concealment, ran away, changed his clothing, and tried to disguise his identity; when arrested, he claimed no memory or consciousness of the act. This claim was clearly not true, and contradicted by the facts.

In a recent case E—— shot his partner in business while both were intoxicated, and displayed great cunning to conceal the crime and person; then, after elaborate preparations, went away. He made the same claim of defence, which was unsupported by any other evidence or facts in his previous life. He was executed. Of course it is possible for the trance state to come on suddenly, and crime be committed at this time; still, so far, all the cases studied show that this condition existed before, and was the product of a growth beginning in brief blanks of a few moments and extending to hours' and days' duration. Unless the facts indicated the trance state before the crime was committed, it would be difficult to establish this condition for the first time, followed and associated with the crime.

I think, in most of these cases, where this defence is set up, there will be found certain groups of cases that have common physical conditions of degeneration. These groups of cases I have divided from a clinical stand-point, the value of which will be more as an outline for future studies.

Probably the largest number of criminal inebriates who claim loss of memory as a defence for their acts are the alcoholic dements. This class are the chronic inebriates of long duration; persons who have naturally physical and mental defects, and who have used spirits to excess for years. This, with bad training in early life, bad surroundings, and bad nutrition, has made them of necessity unsound, and liable to have many and complex brain defects. Such persons are always more or less without consciousness or realization of their acts. They act automatically only, governed by the lowest and most transient impulses. Crimes of all kinds are generally accidents growing out of the surroundings, without premeditation or plan. They are incapable of sane reasoning or appreciation of the results of their conduct. The crime is unreasoning, and general indifference marks all their acts afterward. The crime is always along lines of previous conduct, and never strange or unusual. The claim of no memory in such cases has always a reasonable basis of truth in the physical conditions of the person. Mania is very rarely present, but delusions and morbid impulses of a melancholic type always exist. The mind, like the body, is exhausted, depressed, and acts along lines of least resistance.

The second group of criminals who claim no memory are those where the crime is unusual, extraordinary, and unforeseen. Persons who are inebriates suddenly commit murder, steal, or do some criminal act that is foreign to all previous conduct. In such cases the trance condition may have been present for some time before, and escaped any special notice, except the mere statement of the person that he could not recollect his acts. The unusual nature of the crime, committed by persons who never before by act or thought gave any indication of it, is always a factor sustaining the claim of no memory. The explosive, unreasoning character of crime always points to mental unsoundness and incapacity of control.

A third group of criminals urge this statement of no memory, who, unlike the first group, are not imbeciles generally. They are positive inebriates, drinking to excess, but not to stupor, who suddenly commit crime with the most idiotic coolness and indifference, never manifesting the slightest appreciation of the act as wrong, or likely to be followed by punishment. Crime committed by this class is never concealed, and the criminal's after-conduct and appearance give no intimation that he is aware of what he has done. These cases have been termed moral paralytics, and the claim of the trance state may be very likely true.

A fourth group of cases where memory is claimed to be absent occurs in dipsomaniacs and periodical inebriates, who have distinct free intervals of sobriety. This class begin to drink to great excess at once, then drink less for a day or more, and begin as violently as ever again. In this short interval of moderate drinking some crime is committed which they claim not to have any recollection of.

Other cases have been noted where a condition of mental irritation or depression preceded the drink explosion, and the crime was committed during this premonitory period and before they drank to excess. The strong probability of trance at this period is sustained by the epileptic character of such conduct afterward. The trance state may be justly termed a species of *aura*, or brain paralysis, which precedes the explosion.

In some instances, before the drink storm comes on, the person's mind would be filled with the most intense suspicions, fears, delusions, and exhibit a degree of irritation and perturbation unusual and unaccountable. Intense excitement or depression, from no apparent cause, prevails, and during this period some crime may be committed; then comes the drink paroxysm, and later all the past is a blank. Trance is very likely to be present at this time.

In these groups the crime is generally automatic, or committed in a manner different from other similar crimes. Some governing centre has suspended, and all sorts of impulses may merge into acts any moment. The consciousness of acts and their consequences is broken up. The strong probability is that these trance blanks begin in short periods of unconsciousness, which lengthen with the degeneration and mental feebleness of the person. The obscurity of these conditions, and the incapacity of the victims to realize their import, also the absence of any special study, greatly increases the difficulty. It will be evident from inquiry that trance states among inebriates are common, but seldom attract attention, unless they come into legal notice. The practical question to be determined in a given case in court is the actual mental condition of the prisoner, who claims to have no recollection of the crime. This is a class of evidence that must be determined by circumstantial and collateral facts, which require scientific expertness to gather and group. The court can decide from the general facts of the crime and the prisoner whether his claim of no memory may possibly be true, and order an expert examination to ascertain the facts. This should be done in all cases where the prisoner is without means, in the same way that a lunacy commission is appointed to decide upon the insanity. The result of this expert study may show a large preponderance of evidence sustaining the claim of no memory, or the opposite. If the former, the measure of the responsibility must be modified, and the degree of punishment changed. While such cases are practically insane at the time, and incapable of realizing or controlling their acts, they should be kept under legal and medical surveillance for a lifetime, if necessary. Such men are dangerous, and should be carefully watched and deprived of their liberty for a length of time depending on recovery and capacity to act rationally and normally. They are dangerous, diseased men, and, like victims of contagious disease, must be housed and treated.

The future of such cases depends on the removal of the causes which made them what they are. The possibility of permanent restoration is very promising in most cases. How far alcoholic trance exists in criminal cases is unknown, but the time has come when such a claim by criminals cannot be ignored, and must be the subject of serious inquiry. Such a claim cannot be treated as a mere subterfuge to avoid punishment, but should receive the same attention that a claim of insanity or self-defence would. This is only an outline view of a very wide and most practical field of medico-legal research, largely unknown, which can be seen in every court-room of the land. These cases appeal to us for help and recognition, and the highest dictates of humanity and justice demand of

us an accurate study and comprehension of their nature and character.

The following summary of the leading facts in this trance condition will be a stand-point for other and more minute investigations:

1st. The trance state in inebriety is a distinct brain condition, that exists beyond all question or doubt.

2d. This brain state is one in which all memory and consciousness of acts or words are suspended, the person going about automatically, giving little or no evidence of his real condition.

3d. The higher brain centres controlling consciousness are suspended, as in the somnambulistic or hypnotic state. The duration of this state may be from a few moments to several days, and the person at this time may appear conscious and act naturally, and along the line of his ordinary life.

4th. During this trance period crime against person or property may be committed without any motive or apparent plan, usually unforeseen and unexpected. When accurately studied such a crime will lack in the details and methods of execution, and also show want of consciousness of the nature and results of such acts.

5th. When this condition passes away the acts and conduct of the person show that he did not remember what he had done before. Hence his denial of all recollection of past events, and his changed manner, confirm or deny his statements.

6th. When such cases come under judicial inquiry the statement of the prisoner requires a scientific study before it can be accepted as a probable fact. It cannot be simulated, but is susceptible of proof beyond the comprehension of the prisoner.

7th. In such a state crime and criminal impulses are the result of unknown and unforeseen influences, and the person in this condition is dangerous and an irresponsible madman.

8th. This condition should be fully recognized by court and jury, and the measure of responsibility and punishment suited to each case. They should not be punished as criminals, nor should they be liberated as sane men. They should be housed and confined in hospitals.

## FLAT-FOOT, OR PES VALGUS ACQUISITUS.

By JAMES K. YOUNG, M.D.,

PHILADELPHIA.

INSTRUCTOR OF ORTHOPÆDIC SURGERY, UNIVERSITY OF PENNSYLVANIA; ATTENDING ORTHOPÆDIC SURGEON, OUT-PATIENT DEPARTMENT, UNIVERSITY HOSPITAL, ETC.

The orthopædic surgeon is frequently consulted about a painful deformity of the foot which, as an acquired affection, is very common, and, as such, has not generally received the attention it deserves. It is the so-called "flat-foot," or talipes plantaris.

Flat-foot is characterized by a falling down or giving way of the normal plantar arch, so that the inner side of the sole rests upon the ground, or is turned completely backward. It has been variously described as talipes valgus, pied-bot valgus of the French, and platt-fuss of the German writers. Like other forms of talipes or club-foot, it may be either congenital or acquired. As a congenital affection, in its mildest form it is often found at birth, but seldom in such a degree as to be considered pathological. It is, moreover, a well-accepted fact that all infants on commencing to walk are flat-footed, and do not acquire a perfect plantar arch until they have exercised some time and the leg-muscles have become developed.

It is most common as an acquired affection from infancy to adolescence, seldom becoming a serious deformity until the latter period, and always occurring in one of two forms, as pes valgus paralytica, resulting from poliomyelitis anterior; or as pes valgus acquisitus, from simple muscular relaxation, as associated with rachitis; or as a sequala of burns, traumatism, osteitis of the tarsus, or ankle-joint disease.

It may be instructive here to review briefly the anatomical construction and mechanism of the natural foot. The foot includes all that portion of the inferior extremity below the tibio-tarsal articulation consisting of the tarsus, metatarsus, and phalanges, and in the adult has the form of two arches, an antero-posterior and a transverse, each with its convexity or dorsal surface above, and its concavity or plantar surface below.

The antero-posterior, the most important, is supported upon two piers or pillars, and has its summit at the astragalus and ankle-joint. This has been still further divided into two arches, an outer and an inner, by an imaginary line drawn posteriorly between the third and fourth metatarsal bones. The inner portion of the antero-posterior arch is much more curved than the outer, and forms the instep.

The posterior pier, formed by the posterior parts of the astragalus and os calcis, is shorter, more curved, has but one joint, and is more solid, receiving the greater part of the weight of the body. The anterior pier, composed of the scaphoid, three cuneiform, and three inner metatarsal bones, is longer, less curved, has many joints, and is more elastic, serving to diminish the force of shocks transmitted to the arch. The head of the astragalus, fitting into the concave surface of the scaphoid, and its postero-inferior surface, articulating with the anterior surface of the os calcis, may be regarded as the keystone, though differing in many respects from such bodies as usually employed. The weak part of the arch is strengthened by the interosseous ligaments, particularly the inferior calcaneo-scaphoid, which supports it from below, while beneath the inner portion of the plantar fascia adds additional strength. The outer portion of the antero-posterior arch consists of the outer portion of the os calcis, cuboid, and the two outer metatarsal bones. It is strengthened by the calcaneo-cuboid ligaments and the outer portion of the plantar fascia. Both arches are still further maintained by the tibialis posticus and peronei muscles, particularly the P. longus. The transverse arch, formed on the inner and outer sides by the bones entering into the inner and outer antero-posterior arches respectively, varies in degree of curvature in different portions of the foot, being most marked across the cuneiform bones. It affords protection to the soft parts of the sole, and adds to the elasticity.

The weight of the body is received by the astragalus as the highest part of the arch, and transmitted to the ground through the two piers of the antero-posterior arches. The foot in extension rests normally upon the heel, the tips of the metatarsal bones, and the outer side of the sole, the weight of the body in standing, walking, running, or dancing being transmitted through the heel, the ball of the great toe, and that of the little toe—the natural tripod of the foot—in the order named.

Thus the direction of the weight upon the arches is constantly changing, and it is only through the action of certain muscles that the normal arches are conserved. Thus in flexion the antero-posterior arch is increased by the action of the tibialis anticus, peroneus tertius, and extensor longus digitorum; and in extension, by the action of the gastrocnemius, soleus, plantaris, and peroneus longus, both the curves are diminished, and the foot flattened. Then, also, when the foot is markedly flexed the foot is adducted, and when markedly extended it is abducted, in which positions the arches are respectively increased and diminished. In this connection, Mr. Le Gros Clark says: "In reviewing the action of the various muscles around the foot, it is obvious that their attachment is designed to preserve the plantar arch, and that such healthy condition must depend in great measure on the evenly balanced action of those muscles upon their several attachments. Thus the peronei and tibial muscles antagonize each other, and the expanded insertion of two of them into the tarsal bones is very instrumental in preserving the transverse as well as the antero-posterior arch."

Three degrees or stages have usually been recognized, a mild, an intermediate, and a severe stage. Thus Lit-

tle[1] describes three varieties, of increasing intensity: 1st, those "in which the displacement is transient during the erect position only;" 2d, those "in which the displacement is permanent, and *deformity* is present;" and, 3d, those characterized by an aggravation of all the symptoms, to a marked degree.

A very good division, also, is that of Roth,[2] who describes three varieties: "(1) Cases in which it is possible to restore the foot completely to the normal shape by passive manipulation, without any force exerted by the surgeon, or by making the patient stand with the heels raised; (2) cases where the tarsal bones have become more or less fixed in their displaced positions by shortened ligaments and tendons, osseous deformity of the articulation surfaces, and fibrous or osseous anchylosis, which require forcible manipulation under anæsthetics to restore more or less of a normal arch; (3) intermediate cases, in which a partial restoration of the tarsal arch is possible without *brisement forcé*."

The division, however, which I prefer is that into, 1st, slight; 2d, medium; and, 3d, severe; which corresponds to that of Reeves.[3]

Numerous theories have been advanced as to the mode of production of flat-foot. The muscles, tendons, ligaments, bones, fascias, and even an improper mechanical construction, have each been considered the chief factors in its production.

Thomas, of Liverpool, and Roth,[4] of London, believe that the normally constructed human foot is incorrect anatomically, because "the lower end of the tibia is placed too much toward the inner border of the foot," and that this is the primary cause. Stromeyer[5] believed that atony of the plantar fascia, and the tarsal interosseous ligaments were at fault.

H. von Meyer[6] considered it due to a rotation of the astragalus inward, and pressure atrophy of the bones; while Reismann[7] considered it due to muscular contraction, first of the extensors and then of the pronators; but Volkmann and Lorenz[8] have disproved this, the latter supporting the view of Henke,[9] who announced that muscular insufficiency and body pressure were the chief factors; an explanation first proposed by Duchenne (of Boulogne), who considered the peroneus longus particularly at fault.

Of these theories the last has always appeared to me the most satisfactory, that it is a muscular affection from the first. Thus muscular relaxation, either from debility or paralysis of the peroneus longus, leads to an improper distribution of the body-weight upon the tarsal arches, which, by undue pressure upon the interosseous ligaments, especially the inferior calcaneo-scaphoid and calcaneo-cuboid ligaments and plantar fascia, induce their subsequent relaxation, stretching, and obliteration of the normal arch.

The symptoms differ in the two varieties—pes valgus acquisitus and pes paralytica—but in each are characteristic; but it is more particularly with the former—the so-called "splay foot," "talipes valgus spurius," "inflammatory flat-foot," or "tarsalgia of adolescents," with which we are concerned.

Patients suffering from this affection have an attitude and walk that is characteristic. They stand with the feet everted, resting on the inner side of the sole, with the knees in a fixed valgoid position, and walk with a difficult, heavy gait, the knees flexed and the feet placed everted and flat upon the ground in an uncertain, careful manner. Such patients have an expression of anxiety, tire easily, and complain of great pain of a dull, aching character, or sharp, excruciating in nature, about the inner malleolus, instep, or ball of the great toe, accompanied in some cases with swelling. On inspection the external appearance varies with the degree. In the mild variety the plantar arch is depressed, the inner malleolus lowered and prominent, the foot is cold, bluish, and perspires freely, and an outline taken to ascertain the angle of deflection[1] is found reduced from thirty-four degrees normal to about twelve degrees in mild, to eight degrees in severe cases.

The patient cannot raise himself on his toes, but the deformity can be readily restored by manual pressure. In the medium variety all these conditions are exaggerated, the foot is completely flattened and somewhat everted, the inner side presents two prominences below and anterior to the internal malleolus, the head of the astragalus, and the tubercle of the scaphoid; and on taking an outline the angle of deflection is found reduced to probably eight degrees. The pain is common about the inner lower portion of the astragalus, and may be so severe as to render exercise intolerable. The arch can still be restored, and the deformity is not prominent.

In the severe variety the foot is more everted, making an angle of deflection in severe cases as low as five degrees. This is due to functional paresis of the peroneus longus, and increased reflex contraction of the peroneus brevis, tertius, and extensor communis digitorum. The pain is increased by the unbalanced action of muscles, giving a painful spot at the base of the first metatarsal bone, by the direct pressure upon the ligaments, giving a point over the calcaneo-cuboid and astragalo-scaphoid articulations, and from direct pressure upon the plantar nerves referred to their distribution. Fibrous and osseous changes have occurred, and the arch cannot be restored without some operative procedure.

The pathology of the affection was for some time obscure, especially the non-paralytic valgus, it being supposed at one time to be inflammatory. Such cases have frequently been mistaken and actively treated for inflammatory lesions of the bones or ligaments; complete inflammation with effusion of lymph, serum, or pus, never, however, occurs. All the inflammatory symptoms are simply the result of pressure.

The extensors, particularly the peroneus longus, from some cause become relaxed. This is followed by stretching and elongation of the plantar muscles and tendons, the long and short plantar ligaments, the calcaneo-cuboid and astragalo-scaphoid ligaments, and the plantar fascia, and a giving way of the inner antero-posterior arch. The astragalus is pushed downward, forward, and inward; the scaphoid is rotated, the internal surface downward and the external surface upward; the ligaments, generally on the inner and plantar surfaces of the bones, are stretched, the joint surfaces separated on the plantar and crowded together on the dorsal aspect. This may become so great that the bones entering into the medio-tarsal (Chopart's) joint divide, the anterior portion resting upon the ground and the posterior portion drawn up by the extensors so that the heel does not touch the floor, making the so-called "canoe-shaped sole." The articular surfaces become eroded from the continued pressure, and osseous anchylosis renders the deformity permanent. The diagnosis in many cases can readily be made, but in others, especially the inflammatory variety, with which we are most concerned, very careful attention will be required to avoid confounding it with other conditions.

From the congenital forms of valgus it can be distinguished by the latter being always bilateral and the peroneus responding to electrical stimulus. (The slight normal tendency to flat-foot observed in infants has already been referred to.) Its occurrence about the period of adolescence, the previous history of rheumatism, knock-knee, bow-legs, lateral curvature, traumatism, bone or joint disease, should all be carefully inquired into.

It is most commonly mistaken for rheumatism, of which it may be a sequela, and for inflammatory conditions of the tarsal or metatarsal joints or ligaments. Its angle of deflection, determined from the outline, will be the best single symptom to distinguish it from the former; and the same with reflex muscular contraction, or a collection of inflammatory fluid, from the latter.

The lesions from which it would be most difficult to distinguish it are the early stages of perforating ulcer, and such neuropathies as Charcot's joint disease. From these in the earlier stages a differential diagnosis cannot be made, but the subsequent course would soon decide the true nature of the affection.

The prognosis will depend on the cause and general condition and surrounding of the patient, and degree of the deformity. If advice is sought early, and the disease is still in the first or even second degree, the prospects, under appropriate treatment, of great improvement or even complete cure are good. Certainly entire relief of pain may be expected. If, however, ligamentous or osseous anchylosis have occurred, some relief may yet be hoped for, but resort must be had to brisement forcé, or tarsectomy, before the deformity can be overcome.

The treatment of pes valgus acquisitus varies with its cause and degree. Any diethetical tendency must be corrected by appropriate remedies. The mild varieties yield readily to the use of electricity to the affected muscles, massage, and removal from the exciting cause, with properly fitted metallic sole plate. For this purpose numerous devices have been recommended—pads of leather, felt, rubber, and other material attached to the inner or outer side of the sole, steel bars, springs, etc., added to specially constructed shoes, etc. I have attained the best results with the improved plate spring of Dr. A. Sydney Roberts, figured in *Medical and Surgical Reporter* for April 6, 1889. It consists of a tempered steel plantar spring so constructed as to supply an artificial arch..

In describing it,[1] he writes:

"An outline of the patient's foot is first taken on stencil-board, the tracing being extended upward on the inner side of the foot. The elevated, corresponding to the depressed, arch of the foot, can be tempered to the extent required by the particular case. The lateral pressure brought to bear by the elevated flanges is such that, while giving support to the arch to a certain extent, the artificial arch also prevents further displacement of the astragalus and scaphoid. Again, in place of giving only a limited amount of support to the inner side of the foot, this appliance supports the foot as a whole."

After the use of this spring in upward of sixty cases, in hospital and private practice, I am much gratified with the results obtained.

In severe cases, after the restoration of the arch by operative measures, the spring may with advantage be supplemented by an ankle support—two lateral steel uprights connected with a band extending to the calf, and an internal oval ankle-pad over the medio-tarsal articulation.

As a symptomatic condition in osteitis of the tarsus and ankle-joint disease, the valgus generally yields to the treatment employed for the primary osseous or articular lesion.

In severe cases, before resorting to extreme operative measures, all contracted tendons should be divided. Those most frequently requiring division will be the tendo Achillis, peronei, and extensor longus digitorum, and they are best divided into two stages—the peronei and extensor longus digitorum, first, to correct the valgus, and the tendo Achillis subsequently, to correct the equinus, which in severe cases is present. Failing in the worse cases to restore the arch by such means, accompanied with manual force—brisement forcé, with either a Bradford or Thomas wrench, should be attempted, and, as a last resort, Ogston's[1] operation should be resorted to; or, if much anchylosis be present, a regular tarsectomy, *i.e.*, removing a wedge-shaped piece of the tarsus from the inner side of the tarsus without reference to the bones or portions of bones removed, and the restoration of the foot. These severe operations should only be resorted to when milder measures, after due trial, have failed; for comparative relief will, in the greater majority of cases, be obtained by the milder remedies in about six or eight weeks, whereas several months are required after any cutting operation upon the tarsal bones.

## Clinical Department.

### HYSTERECTOMY FOR LARGE FIBROMYOMA.

By D. BENJAMIN, M.D.,

SURGEON TO THE COOPER HOSPITAL, CAMDEN, N. J.

H. M——, aged thirty, living in the southern part of New Jersey, came to me, March 24, 1888, suffering from a large abdominal tumor which, she stated, her physicians called an ovarian tumor. I obtained the following history: Her mother died of erysipelas; one sister died with cerebro-spinal meningitis. Patient's past condition was stated to have been moderately healthy until last summer, when she commenced to lose flesh; at this time there was noticed a slight enlargement of the abdomen, which was attributed to dropsy. In October, 1887, she was examined by a physician, who stated that there was a tumor in the left ovarian region, then about the size of a fist. Two months afterward she was subjected to another examination, and the tumor was found to have increased in size to that of a child's head. No history of any injury to this region could be obtained. Her menstrual flow had been regular, sometimes profuse; had skipped one month, which she attributed to a cold. She began to suffer from vomiting, and constipation, and occasional abdominal pains; these symptoms had constantly grown worse, until almost every meal was vomited, and constipation became more and more obstinate, so that powerful purgatives had to be administered, but were losing their effect, and symptoms of obstruction were becoming marked.

She had lost fifty pounds in weight within a few months, but as she had been previously inclined to embonpoint, her emaciation was not extreme. On palpation through the abdominal wall, the tumor appeared symmetrical and mobile; did not feel so hard as is common with fibroid tumors, nor so soft as a cyst; was not nodular, and felt very much like a pregnant womb in the early part of the ninth month. Fluctuation could not be positively demonstrated. Percussion sound dull, except a small area in each flank.

Vaginal examination showed the cervix drawn up, and an enlargement in Douglas' pouch about the size of a retroverted womb. Rectal touch gave no additional information. A flexible urethral sound passed into the os uteri about two inches, taking a forward direction. Pregnancy having been eliminated by the examination, a diagnosis of solid, or semi-solid tumor involving the womb could be made, but the exact relation of the ovaries to this tumor was not clear, and exploratory incision was advised, with a view of ascertaining the exact relation of the tumor to the pelvic organs, and the possibility of its removal, with the understanding that any beneficial operation that would seem feasible should be proceeded with. Accordingly, March 29th, patient was etherized; the usual incision was made in median line. The tumor was wedged so tightly in the superior strait of the pelvis, that only one ovary could be reached—the left, which was enlarged. Adhesion being slight, the incision was extended upward, with scissors, sufficiently to enable the upper part

of the tumor to be reached, which was free, but in contact with the stomach and liver.

The incision was then extended upward and downward sufficiently to enable the tumor to be delivered forward through the abdominal incision. The right ovary was found crowded down into Douglas' pouch, and was enlarged to about the size of a hen's egg, and roughened on the surface. The right Fallopian tube was much enlarged, and the left tube was about double the normal size, and adherent. Both ovaries, and both Fallopian tubes were carefully ligated and cut away. The exact relation of the base of the tumor to the womb could now be clearly made out, and it was apparent that room enough could be made above the insertion of the vaginal wall, into the cervix, to remove the tumor and body of the womb without necessarily wounding the ureters, bladder, or other pelvic organs. I then determined to remove the entire tumor and womb, since to return it to the abdominal cavity would have been to have left the patient in almost as bad a condition as before the operation, with respect to the obstruction and other difficulties which the tumor caused, and at the same time be little less dangerous to the patient's life than complete hysterectomy. I then carried the incision downward as closely to the pelvic bone as the bladder would permit, ligated each of the round ligaments in two places, and cut between, applied Koeberle's clamp, and cut away the tumor. The stump was at least three inches in diameter. The tumor was about thirty inches in circumference. After all bleeding points had been properly secured, and all clots removed from the abdominal cavity, the bowels and peritoneum were thoroughly washed off. The omentum, which had been lying on a towel, was returned and arranged over the bowels. The pedicle was fixed in the lower angle of the womb, and the incision closed with silk sutures at intervals of less than half an inch. Wound was dressed antiseptically, and the patient placed in bed.

The patient constantly improved without any untoward symptoms, and was discharged in six weeks after the operation. The clamp came off on the twenty-third day. The patient has not vomited since the operation, and has had no pain. All functions are normal. She states that it is the first time she has felt well in four or five years.

In determining the value of the operation of hysterectomy to humanity, it is important that all cases should be reported, as I found the literature on the subject so meagre at the time of the above operation, that reliable data could not be obtained in this country. The operation has never, so far as I can learn, been performed in New Jersey; but as hysterectomies are becoming more frequent and successful, ample statistics will soon be forthcoming.

## A CASE OF STRANGULATED HERNIA MISTAKEN FOR ONE OF URÆMIA IN A PATIENT KNOWN TO BE SUFFERING FROM CHRONIC INTERSTITIAL NEPHRITIS—AUTOPSY.

By FREDERICK REMINGTON, M.D.,

ROCHESTER, N. Y.

N. F——, sixty years of age, married and housekeeper by occupation, entered the Monroe County Insane Asylum suffering from chronic mania. The family and personal histories were negative; the habits unknown; and the previous health good. She was well developed and nourished. Heart enlarged to left. Accentuation of second aortic sounds. Some œdema of hands and feet and some puffiness of eyelids. Examination otherwise negative.

Urine—Amount varied from 70–90 ounces in 24 hours. Specific gravity, 1.010–1.008. Albumin $\frac{1}{8}$–$\frac{1}{16}$ of one per cent., and the sediment contained a relatively large number of small hyaline and fine granular casts. During the patient's stay in the asylum she frequently suffered from slight uræmic attacks, as was evinced by some œdema of feet and eyelids, vomiting, and vertigo. From these attacks she usually recovered after a rest of a day or two in bed.

The patient's appetite had been poor for several days, and she had been losing weight rapidly. One day she had some swelling of feet and vomiting; there was also diarrhœa. Morphine, gr. $\frac{1}{4}$ by stomach, was given to relieve the vomiting. The urine was passed involuntarily and its amount cannot be estimated. During the next two days the patient's symptoms grew rapidly worse, and she died three days later at noon. No new symptoms having developed.

*Autopsy.*—The heart-walls were greatly thickened, and showed evidence of granular degeneration. There was calcification of the aortic flaps. The mitral orifice admitted five, and the right auriculo-ventricular seven, finger-tips. The weight of the heart was twenty-two ounces.

The kidneys were decreased in size, their surface was uneven and capsule adherent; surface granular; cortex is very much decreased and dense on section; pyramids injected; weight of both kidneys five ounces.

Projecting through the internal inguinal ring on the right side, into the inguinal canal, there was a hernia of the middle portion of the small intestine. The intestines were agglutinated to the hernial sac. The included knuckle of gut was gangrenous and leathery, and easily broken through. The hernial sac contained about two ounces of a yellowish stercoraceous material. It was impossible to reduce the hernia. Below the constriction, the intestines were empty, while above they were filled with gas and semi-fluid, yellowish, not especially feculent, fæces. There was absolutely no tumor produced by the hernia, and there was no symptom which was not in keeping with a uræmic attack. Of course, the patient was unable to give satisfactory subjective symptoms, and under the circumstances a more rational conclusion could not have been arrived at than the opinion formed by everyone who saw her, that she was suffering from uræmia.

## SUBCORACOID DISLOCATION OF THE HUMERUS REDUCED BY KOCHER'S METHOD.

Dr. S. W. Boerstler, of Lancaster, O., writes: "P. M——, a stout, muscular man, was brought to my office with a subcoracoid dislocation of the left humerus, produced by a fall on the hand and forearm, a few hours before I saw him. Several attempts at reduction had been made by manipulation, extension outward and downward with the heel in the axilla, but all failed. Having read the account of Kocher's method in The Medical Record of March 30th, by Dr. Charles Powers, of New York, I concluded to give it a trial. The patient was placed on the floor, the well shoulder steadied by an assistant, and the position of the arm, with the different movements as shown in Dr. Powers' article, strictly carried out. The first attempt was successful, and those present, as well as myself, were astonished with what ease and facility the reduction was accomplished. I had never heard of Kocher's method, and I believe it is not generally known to the profession. Our text-books on surgery do not speak of it. Hamilton, in his work on 'Fractures and Dislocations,' recommends reduction by manipulation, but the different movements of the arm are unlike those of Kocher. This simple, easy, and effective procedure, I advise every one to try who may have a case of subcoracoid dislocation. It is unnecessary to anæsthetize the patient."

The Brooklyn Academy of Science, a society incorporated August 22, 1888, has opened a free reading-room in its rooms in Warner Institute, Willoughby Avenue and Broadway, Brooklyn. The various scientific journals will be upon the tables, and there is absolutely no charge to the public. Donations of papers will be greatly appreciated.

## THE WORKINGS OF THE LAW AGAINST SUICIDE.

DOES prohibition prohibit? is a question frequently asked, in these days, by those interested in temperance matters, and is variously answered according to the bias of the one to whom it is addressed. A similar question was propounded a few years ago when a law was passed in this State making suicide a crime, and many inquired, doubtingly, whether the attempted prevention of suicide would prevent it. If it is allowable to form a conclusion from the statistics of suicide in this city, we might say that it does prevent, or rather restrict, self-murder. Previous to the enactment of this law the average number of suicides in New York City was 144 per 1,000,000 inhabitants, and since that time, although there has been an increase in the number of suicides, the increase has not been in proportion to the growth of population, so that, relatively, there has been a slight falling off.

The punishment prescribed for attempted suicide is not very severe, and would not be likely to deter one who was really bent on self-destruction. The section of the Penal Code bearing upon this point reads as follows: "Every person guilty of attempting suicide is guilty of a felony, punishable by imprisonment in State prison not exceeding two years, and by a fine not exceeding one thousand dollars, or both."

The fact that such a mild penalty has had the effect of reducing the number of suicides relatively to the population suggests the query whether, in a certain proportion of cases, the success of a suicidal attempt is not accidental; whether of those that perish a certain number did not make a feint at suicide without really intending or wishing to end their lives, led to their foolish act perhaps by a desire to create sympathy, or in the hope of calling back an offended lover, the feigned attempt becoming, unfortunately, only too real in its fatal issue. This supposition is strengthened somewhat by the statistics of the Board of Health in respect to the class in whom the greatest falling-off in suicide has been noted. It is shown that the decline is most notable in women, and it is among the weaker ones of this sex that we would most naturally look for these pretended attempts at self-destruction. Having no intention of killing themselves, they would be more likely to be deterred from making a pretence of so doing by the threat of a punishment held over them, whereas those who really wished to end their existence would be little influenced by a penalty which they would take care to escape by insuring a successful termination to their attempt.

## THE LESSONS TAUGHT BY RARE DISEASES.

A VERY instructive address was recently delivered by Jonathan Hutchinson (*Lancet*, May, 1889) before the Medical Society of London, in which he urged upon his hearers the importance of careful and systematic study of rare diseases. There are no isolated maladies, all diseases are the result of pathogenetic influences, and careful study will often show the relation between widely differing appearances. A large number of diseases ranked as "rare" are simply exaggerated or overgrown examples of those which are common—more striking, it is true, but presenting nothing really novel. The zeal which we often witness for "nominal" diagnosis, the anxiety to place every case under some recognized name, leads sometimes to forgetfulness of the fact that the nature of the disease is of far more real importance than its name. In the early stages of most maladies, the ulterior development is by no means certain, but depends rather upon the—as yet undetermined—incidence of a variety of contributory causes. It is not the fact that the human body is ever taken possession of by some seed-like principle, destined in future infallibly to evolve a certain definite form of disease. The form which results is the outcome of a complex chain of causes. The order of events which has in any given case ended in the production of certain of these rare maladies, might have failed at any point, or might have been broken by art.

As illustrations of this truth, he cites a number of interesting diseases. The starting eyes, the throbbing carotids, the swollen thyroid, the irritable heart, the general failure of strength in exophthalmic goitre, mark the extreme development of the disease; but every day we see women with failing health, and irritability of circulation in head and neck—shown by want of control of temper and proneness to flushing—who, in all probability, are suffering from the same disease in its mildest form. Change of climate is, probably, the only specific: in the former case, giving the greatest relief to symptoms, in the latter, cutting the disease short in its earliest stages.

In myxœdema, we have a slowly insidious change in structure, pervading almost all parts, and leading, without any tendency to spontaneous amelioration, to gradual abolition of all the higher endowments of humanity, and, finally, to destruction of life itself. But who does not see frequently in the flabby, thickened skin, the featureless face, the general obtunding of intellect of certain patients, the milder forms of this disease, which, we may be tempted to suspect, is, in reality, but one of the ordinary forms of premature senility to which many women are, to a greater or less degree, liable.

While some of the diseases accounted rare are simply exaggerated specimens of what is common, it is also true of others that they reveal individual idiosyncrasies of exaggerated intensity. In xeroderma pigmentosum, for example, the affected children are born with apparently healthy skins, but in a few years freckles develop on exposed parts in a most unusual degree, and these may coalesce, become inflamed or ulcerated, destroy the features, produce neoplasms, or even become cancerous.

But this disease is essentially the same as common freckling, only intensified by the family peculiarities of the patient.

This doctrine of exaggeration, as explanatory of rare diseases, is very well illustrated by the phenomena of Reynaud's disease. All the changes that are essential to it are experienced by the person who gets a "dead" finger from keeping his hand in cold water, or a blue nose from exposure to a cold wind.

Again, xerostoma is but a more pronounced and persistent example of that temporary dryness of the mouth which is so often induced by emotion.

In one case under his own observation, a patient, after an ordinary operation for piles, had immediate, complete, and permanent paralysis of the anus and urethra. In his opinion similar disabilities of the rectum and bladder centres, in less degree, occur in all cases of retention after operations.

It is important that we should understand that no diseases are unique. When like causes are brought to bear, like results must necessarily ensue. If we but look around us enough, and reflect upon what we see, we shall discern the great laws which underlie all disease processes. The transformation of the "black freckles" of the aged into cancer and similar phenomena but illustrate two great laws—that in the processes of old age, all local disturbances tend toward cancerous action, and that the precise form of malignancy will depend on the tissue attacked.

In this connection, the condition termed "granuloma fungoides" deserves mention. The skin is first attacked by inflammatory thickening, and then, gradually, large fungating growths develop, which are in all clinical features malignant, and which cause the patient's death. These are neither epithelial nor sarcomatous, but seem to be connecting links between inflammatory and truly malignant affections. Some of them may possibly have derived their peculiarity in the first instance from individual idiosyncrasy as regards drugs.

Several of the many rare diseases quoted in his address illustrate strikingly, in his opinion, the important doctrine that all inflammatory products are infective, much in the same way that the products of malignant growth are so; and further, that the process of malignant new-growth is, after all, nothing but a modification of that of chronic inflammation.

## THE TRUE STATUS OF HOMŒOPATHY.

THE New York *Graphic* recently wandered from the easy paths of contemporaneous picture-making, and made some remarkable statements regarding the status of homœopathy. Commenting on Professor H. C. Wood's address at the Yale Medical School, it says: "At a time when quite one-half of the medical practice of the world is governed by the philosophic discoveries of Hahnemann, it seems something more than an anachronism to have a member of the Faculty of the Pennsylvania University stigmatize homœopathy as quackery on the plane of faith-cure."

The *Graphic* critic adds: "Considering that there are monuments to Hahnemann, the discoverer of homœopathy, in many of the great cities of Germany—that the science he taught is a recognized branch in most of the great medical schools in Europe, Professor Wood's extraordinary doctrine, must be regarded as the zeal of ignorance and does no credit to the great university he compromises by such intemperate judgment."

Such stupid and blundering criticism as this is of importance and interest only as it shows how prevalent is the ignorance regarding the true status of homœopathy even among men who are undoubtedly well-informed as to the world's progress in most directions.

The facts are simply these. In the United States there were in 1885 twelve homœopathic and eighty-eight regular medical colleges with one thousand and eighty-eight and nine thousand four hundred and forty-one students, respectively. At the most liberal estimate the homœopathic practitioners of this country form one-eighth of the total number. There is no homœopathic medical college in the country which can be said to be even fairly well equipped and endowed, as compared, for example, with the leading regular medical colleges of New York, Boston, and Philadelphia. The only school which really flourishes numerically is in Chicago.

The statement that "homœopathy is a recognized branch in most of the great medical schools of Europe" is absolutely untrue. Homœopathy has no place whatever in any of the universities of Germany or France, nor has it a school of its own anywhere in Germany. There is a small homœopathic hospital of one hundred beds in London, with a small medical school attached.

There are said to be only about two hundred and seventy-five homœopathic physicians in all Great Britain and Ireland. The number on the Continent is proportionably even less.

## OLD-TIME FEES.

THE recent centennial celebration of our city seems to have stimulated considerable delving into the past, and medical matters have had their share of investigation. Chiefly among these, aside from the questions of modes of prescribing and treatment, fees have claimed no little attention. One fact, at least, is patent, that, as a rule, they have not increased, and in very many instances have perhaps fallen below the stationary plane. At best, to the general practitioner, upon whom the burthen of earnest and continuous work mostly falls, the consideration of what is a proper recompense for services is of paramount interest. For his consolation, we may say that in the golden days of our continent medicine, no more than theology and law, yielded no princely incomes. Perhaps medical societies here and there may have attempted to regulate the scale of remuneration by imposing rates with carefully shaded details, but these were not uniformly operative, and very likely represented only the maximum. The ancient practitioner, almost invariably "expected to be at home very shortly," dealing with long distances and precarious meals, and facing storms of every derege of severity, even if he charged more than his descendant of the towns of to-day, was compelled to balance his time against competition. Then, again, barter more frequently than money was the basis of settlement, so that shifting values exercised a baneful influence in more ways than one.

Dr. J. M. Worthington, of Annapolis, Md., has sent to the writer of "Medical New York in 1800" a bill of Dr. James Murray's against an estate, studded with various dates from April, 1788, down to its legal settlement in August, 1790.

The comments of our antiquarian friend Worthington upon this bill will explain themselves. He says, in his note to Dr. John Shrady, that the said Dr. Murray, who belongs to the family of that name resident in Maryland many years before the Revolution, collected about five dollars for each visit. "His charges," says he, "for compounding prescriptions, from one shilling to seventeen shillings each, were by no means unreasonable, and yet they would make the average apothecary of to-day wealthy, while the patients might be reduced to despair. As will be seen, all kinds of medicaments figured among the items of this bill; to wit, pills, powders, boluses, blisters, mixtures, infusions, cordials, purges, decoctions, and juleps."

All these things were possible in the days of no coal, no artificial light but candles, no transportation except by horse or sail, and no cheap postage; when, to say nothing about a medical periodical, even a newspaper was a luxury.

The Dr. Murray to whom allusion is made was a man of acknowledged social standing, skill, and learning: he had an extensive patronage among the large land-owners. The recent Surgeon-General of the Army belongs, as we are informed, to this stock.

## News of the Week.

An Accessary Thyroid Gland at the Base of the Tongue.—Herr R. Wolf, of Hamburg, reported a unique case of this kind. A girl, aged eighteen, otherwise healthy, complained of a feeling of a foreign body being in the throat. The speaker found a tumor at the back of the tongue, different in color from the other parts. It was firm and solid to the touch; its posterior border was lost in the gullet. Treatment with iodide of potash and painting with iodine was successful at first, but the tumor suddenly began to grow, difficulty of swallowing came on, and extirpation was determined on. He first performed tracheotomy, and later on (February 6th) removed the tumor. The cavity left was filled with a tampon, and recovery was rapid.

Preventing Tuberculosis by Military Orders.—The German War Minister has decided that the chest of every soldier shall be examined once a month. If the chest does not reach a certain breadth and does not develop with drill and athletic exercises, the soldier will be disqualified, and regarded as being predisposed to phthisis, and, moreover, likely to infect his comrades.

Novel Treatment of Abdominal Aneurism.—A novel procedure has just been attempted by Mr. Keetley in a case of large abdominal aneurism which is under his care at the West London Hospital. The tumor, which mainly occupies the epigastric region, and projects prominently forward, has thrust the liver into the right lumbar region, and Mr. Keetley, in order to control if possible the pulsation in the aneurism, devised and carried out the following procedure. An incision was made below the ribs on the right side, and the peritoneal cavity opened; a specially constructed instrument with a handle, a curved stem, and a thickened extremity was then passed into the wound and through the foramen of Winslow, between the liver and the tumor, and made to compress the aorta above the origin of the cœliac axis. Upon the first occasion the stem was of copper, and unfortunately bent under the pressure to which it was subjected. The operation was repeated with an instrument constructed of steel. It was found that the object aimed at could be obtained, but not entirely. Although the aorta was by this means partially compressed, it was not possible to control the circulation sufficiently to render it justifiable to continue the attempt.—*Medical Press.*

Identity of Function of the Two Occipital Lobes.—M. Dupuy has recently shown a patient before the Société de Biologie who has two good non-strabismic eyes, but who only sees with one at a time. The moment she attempts to use both together she becomes very dizzy; hence, says M. Dupuy, there must be identity of function in the visual centres of each cerebral hemisphere. We do not know that there is any place but the city of Paris in which it would be necessary to prove so old and well-established a fact as that upon which M. Dupuy thinks he has thrown such brilliant light.

An Attempt to Organize an Infirmary for Electro-therapy and "Suggestion-therapy" (Electricity and Mind-cure) was recently made at Munich, but so far has not succeeded.

The Medical Association of Alabama forbids its members to do contract practice. Dr. W. C. Cross contracted to practise with the Blocton Iron & Coal Company, and sent in his resignation as a member of the Association. The resignation was not accepted, and Dr. Cross was dropped for "unprofessional conduct." Thereupon he sued the Association for $50,000 damages. We trust that the Association will not be mulcted in so large a sum; but it seems from the facts before us as if its action was decidedly arbitrary, and a good deal of the Knights-of-Labor order.

Salol and Cholera.—Professor Löwenthal, who has lately made experiments on the action of salol on cholera bacilli in Professor Cornil's laboratory in Paris, of which an account was given in these columns in "Medical Paris of To-day," has received a special mission from the French Government to proceed to Tonquin, in order to study the effects of salol on cholera patients. Professor Löwenthal is for this purpose nominated a navy medical officer *à titre d'étranger*, but is allowed full liberty of action. This is the first time that the French Government has selected a member of another nation for such a post, and it well indicates the tendency of science to draw nations nearer together.—*Lancet.*

Lady Kortright, formerly of Philadelphia, but now living in England, has presented $100,000 to the Presbyterian Hospital at Philadelphia, to found a Convalescents' Retreat. She has also given to the same hospital $40,000 to build a male surgical ward, and $10,000 to endow two perpetual free beds.—*Medical News.*

A Cure for Snoring.—Dr. John I. Brinkerhoff, of Auburn, N. Y., writes: "I notice in The Medical Record a serious request for cure for snoring, and a facetious reply to 'bite the nose, gently, but firmly.' Still, there is a cure for snoring, used by my comrades in the army, viz., tie a band or handkerchief over the mouth if the subject can breathe easily through the nose. We found this to be very effective."

THE EYESIGHT OF AMERICAN SCHOOL CHILDREN.—Dr. J. L. Minor, of Memphis, Tenn., reports (*Memphis Journal of the Medical Sciences*) the results of his examination of 682 pupils in the public schools of Memphis. The refraction was normal in 523 out of 682; the refraction was hyperopic in 128, and myopic in 32. The myopia, therefore, amounts to less than five per cent., and the myopes were all in the fourth class, where they constituted fifteen per cent.

DR. CHARLES F. STILLMAN, of New York City, who has attained considerable prominence during the last eight years in the field of medical examination for life insurance, having been elected to fill the first chair on that subject ever created (in the University of Vermont), and who is also the author of the latest and most thorough text-book on life insurance examinations—besides having been connected with the Travellers' and other prominent companies in this city, as medical examiner—has recently given up this portion of his work, and is now devoting himself to the practice of his specialty.

THE DEATH OF DR. CHARLES W. WOLFERTZ.—Charles W. Wolfertz, M.S., M.D., of 231 East Eleventh Street, died suddenly of heart failure, on June 19th, at Orange, N. J., where he had gone the week previous to regain his health. He was a graduate of the College of the City of New York of Class of 1883, taking degree of B.S. He graduated from College of Physicians and Surgeons in 1886, winning the first Harsen Prize for best Report of Medical and Surgical Clinics held at New York Hospital. He was an inspector of vaccination on Board of Health for three years, and had a promising career before him. He leaves a widow and one child, and a host of sympathizing friends.

FOR DIABETES Dr. Dujardin-Beaumetz says: Into a glass of Vichy water, sweetened with saccharin and flavored with a little rum or kirsch, I dissolve one of the following powders, and order the whole to be taken at one dose: Antipyrin, 3 v.; divide in chart. No. xx. One powder three or four times a day. I have never seen any ill results from this medicine, however long continued; nevertheless, Albert Robin affirms that at the end of a week albumen will appear in the urine. He adds: The most simple way of prescribing Martineau's remedy is: Take before each meal, in a tumblerful of Vichy or Vals water, one of the following powders, adding to the mixture two drops of Fowler's solution of arsenic: Carbonate of lithia, 3 ijss.; divide in chart. No. xx.

PROPOSED EXTENSION OF COLLEGE TERM IN CANADA.—At the recent meeting of convocation of the University of Toronto, the President of the Medical Faculty urged upon the Minister of Education, who was present and who largely controls educational legislation in the province of Ontario, the desirability of having the college term extended to nine months instead of six months, during each of the four years required before graduation. This proposed change is now exciting considerable comment among the profession, and is generally received with favor. The standard of medical education in Canada has steadily increased for many years, and the suggestion of a nine months course, coming as it does from the head of one of the leading institutions, has much to support it. There is no doubt that the present course favors the cramming system so detrimental to the mind and future usefulness of the student. If the course be changed from six to nine months in each of the four years, there is no doubt it will add to the thoroughness of the work done, and will be profitable for the student as well as of advantage to the public, for whose service he will be all the better qualified. While it may seem hard to impose on the student an attendance on college lectures of thirty-six months before being allowed to be presented for graduation, yet few are found willing to dispute the fact that the change would be a most desirable one, and in every way conducive to the interests of the profession in Ontario.

THE LAST INTERNATIONAL MEDICAL CONGRESS, which met in Washington in 1887, unanimously selected Berlin as the next place of meeting in 1890. Professors Virchow, Von Bergmann, and Waldeyer, to whom was confided the preliminary direction of the next congress, have already taken active steps to make it a success. All the medical faculties and other medical bodies in Germany have been invited to nominate delegates to confer together on the subject this year, at the time of the Heidelberg meeting of the German Scientific Association in September. It is proposed that the congress of 1890 should commence its proceedings on August 6, 1890.

THE GYNECOLOGIST'S FIELD.—The Fallopian tubes are found diseased in one-third of all female cadavers, according to Winckel. The gynecologist has, therefore, always one chance out of three of finding something the matter with the ovaries and tubes, if he only cuts down upon them.

VERMONT STATE MEDICAL SOCIETY.—The semi-annual meeting of this society will be held at Brattleboro, Vt., on Tuesday and Wednesday, July 9th and 10th.

THE PRINCE OF WALES' LEPER.—The chief sensation of the week, telegraphs the London correspondent of the *New York Times*, has been over what has come to be called the Prince of Wales' leper. By some curious freak London took exceptional interest in the circumstances surrounding Father Damiens' death. After his death the photographer who owned a negative of the devoted priest coined money, and the agitation began for a moment. The Prince took charge of the matter, and then the doctors who had views on leprosy joined it, and by the time the meeting was held a full-grown project of founding a leper hospital in London had taken shape. Unfortunately, to have a good leper hospital one needs lepers, and so a search was instituted, and the discovery made that there are two much needed specimens in London. The Prince, put up to make a speech, declared that there was a leper in London employed in a large meat market. At this a fearful outcry was raised by the butchers, and columns of protest were crowded into the papers until the identity of this man was revealed. He turns out to be a native Englishman who was never out of the country, and who peddled ox-tails, etc., on his own account, and is an undoubted leper.

HYPNOTISM IN ART.—The novelists who have been of late years working hypnotic and trance phenomena into their productions are being followed by the painters. A Munich artist has recently painted the picture of a beautiful woman lying in a cataleptic state, with the title "Hypnotized."

### FORTIETH ANNUAL MEETING,

*Held at Newport, R. I., June 25, 26, 27, 28, 1889.*

(Continued from page 727.)

### SECTION ON SURGERY AND ANATOMY.

THIRD DAY, THURSDAY, JUNE 27TH.

DR. THOMAS S. K. MORTON, of Philadelphia, read a paper entitled

ABDOMINAL SECTION FOR TRAUMATISM,

in which he carried his original statistics and observations of two and one-half years ago up to date.

He excluded all cases where section for traumatism was not done as a measure of primary relief—that is, at latest, when not more than two or three days have elapsed. Those operated upon after such lapse of time were termed "secondary section," etc.

Of the first class Dr. Morton presented tables of 234 cases, with a general mortality of 58.97 per cent.

Ninety-seven American surgeons operated upon 165 cases, with a mortality of 65.45 per cent.; 64 foreign surgeons operated upon 69 cases, with a death-rate of 47.82 per cent.

Thirty-two operations were performed in Philadelphia, 25 in New York, 22 in St. Louis, 22 in London, and 13 in Chicago.

A feature of the paper were the remarks upon the causes of death after operation. Forty-three cases died from peritonitis, due to delayed operation; 16 from peritonitis arising after operation; 11 from overlooked perforations; 4 from inefficient suturing of wounds; 3 died upon the table, 10 immediately after leaving it, and 40 within 12 hours.

Eighteen cases were opened, and no intraperitoneal injuries requiring treatment found, 2 of which died: 1, of opium-poisoning; the other, cause not stated.

Of the 234 cases there were: Gunshot wounds, 110, mortality, 67.2 per cent.; stab-wounds, 79, mortality, 39.2 per cent.; ruptured bladder, 27, death-rate, 62.9 per cent; ruptured and contused intestine, 18, with an 88.8 per cent. mortality.

Resection of intestine was performed 17 times in 15 cases, with but two recoveries. The writer stated his belief that these, as well as many other figures, would be reversed by the employment of Senn's improved methods of intestinal anastomosis and suture, which he described in their relation and application to wounds of the class under consideration.

Senn's hydrogen test was used in 11 instances. It proved the presence of wounds in 8 cases, their absence in 2 cases, one of which died of subsequent violent peritonitis. In one case it entirely failed to show perforations, two of which were discovered when the abdomen was opened to control hemorrhage. The author assigns the hydrogen test to an extremely narrow field of usefulness.

He emphasizes that, under fair surroundings, every case where penetration can be proved should be opened and searched—many even without such evidence, as in rupture of the bladder, bowel, etc.

He further insists upon median incision, early operation, systematic search for lesions, irrigation, thorough drainage, preliminary washing out of the stomach, and the treatment of subsequent peritonitis with active cathartics and, perhaps, reopening the wound.

Hydrogen insufflation as a test of rupture of the bladder was suggested, and a number of successful experiments to that end cited.

JOSEPH W. PRICE, of Philadelphia, read a paper on

PELVIC SURGERY BY ABDOMINAL SECTION.

The introduction of Listerism, which was fundamentally correct in idea, wrought death by chemicals instead of dirt. Even now this opinion may be disputed. But ere long it will be the rule to keep harmful disinfectants as far away from the abdomen as fetid pus or other filth. It stands proven that cleanliness may be and constantly is obtained without the aid of any chemicals whatsoever. This opinion I have always held, and have never, in any operation of my own, used chemical disinfectants in any form whatsoever. Cleanliness, water, and good surgery are the very best of all antiseptics.

The author then made a strong plea for early operation, and against the use of electricity.

DR. J. M. BALDY, of Philadelphia, read a paper on

THE TREATMENT OF PERITONITIS.

That peritonitis is a disease distinct, and is idiopathic in its origin, is boldly disputed *in toto* by many, their opinion being based on not only clinical and post-mortem evidence but on data obtained by an opening into the peritoneal cavity during life and during the progress of the attack itself. That peritonitis is absolutely never idiopathic in its origin he was not, as many others were, fully prepared to say, but of this, at least, we are sure: that in the vast majority of cases there is a distinct lesion as the exciting cause, and, personally, in quite a large experience with this disease, he had never seen a case in which a definite cause was not probably present. If we accept this view of the etiology of peritonitis, as he thought we needs must, it is perfectly clear that, even from a theoretical point of view, we must find some other treatment than by narcotics.

In place of the treatment by opium large doses of the salines are advised. And this, taken together with opening of the abdominal cavity, put into the hands of the profession remedial agents to which the vast majority of cases of peritonitis should succumb.

Pure traumatic cases, of course, demand operative measures; and chronic peritonitis is best treated by the surgeon. Tubercular cases are no exception to this rule.

After every abdominal section for peritonitis, whether the cause is found or not, the necessary complements of the operation are free irrigation and drainage.

DR. N. B. CARSON, of St. Louis, read a paper on

CHYLOUS CYST OF MESENTERY, WITH A REPORT OF A CASE.

The patient was first seen three years ago, then thirty-nine years of age; had a cyst about the size of a fœtal head. The tumor was aspirated, and several ounces of chyle withdrawn. During the following three months there was no change in the size of the cyst. He was not seen again until February, 1889, when there was found inflammation about the tumor, which had increased in size to that of an adult head. Laparotomy was performed on March 3, 1889, the sac incised, and emptied of five pints of pure chyle.

Analysis by Dr. Bremer, of St. Louis: Specific gravity, 1.014; alkaline; contained albumen, but no fibrin. Microscopically, large granular cells in abundance, in some of which the protoplasm showed various degrees of degeneration. The chief elements were fat-globules, resembling in size those of milk, and also crystals of sodium chloride, carbonates, and sulphates.

Dr. Bremer considers the fact that cells containing fresh and intact protoplasm were found would go to prove that the cyst from which the fluid was taken was in some way connected with the canal carrying fresh cells, probably with the lacteals or the cisterna mesenterica.

This is the first case in American literature, and the largest of all cases recorded to date. These cysts may originate from five different sources: From the thoracic duct, from the receptaculum chyli, from the lacunæ mesentericæ, and from a rupture of the chyle-ducts within the mesenteric folds.

The case resulted in a complete cure. The conclusions are: Removal of these cysts is advised so soon as they begin to inconvenience the patient or interfere with his nutrition or health, by incision and drainage, instead of extirpation, as it is believed that the latter operation is not only difficult but endangers the life of the individual.

DR. ADDINELL HEWSON, of Philadelphia, read a paper entitled

THE USE, TWENTY-FIVE YEARS AGO, OF POLARITY, FOR LOCATING THE WHEREABOUTS OF A LEADEN BULLET DEEPLY EMBEDDED IN THE BODY.

The bullet was located by the agitation of the needle of a small compass-charm when held in the immediate neighborhood.

DR. THOMAS H. MANLEY, of New York, reported a

RARE CASE OF FRACTURE OF THE EXOSTOSIS OF THE PUBIC BONE.

The patient had been well up to three weeks before first seen, and he was able to walk when he was admitted to the hospital. The history was that he had felt something in the groin give way, and the disability followed. A collection of pus presented along the upper inner border of the thigh. This was opened. At a later operation there was found a reduplication of the pubic bone, which had become separated from its base of attachment, and was acting as a foreign body and pressing on the femoral artery. It is the opinion of the writer (the patient having died of pyæmia on the fifteenth day, and a post-mortem examination having been obtained) that the condition was one of congenital reduplication of the pubic bone.

DR. ROBERT NEWMAN, of New York, read a paper entitled

ELECTROLYSIS IN THE TREATMENT OF STRICTURE OF THE RECTUM.

Twelve cases were reported in detail; the first had been treated by him in 1871. The *modus operandi* is virtually the same as he uses in urethral stricture, applying a metal bulb as negative pole to the stricture with a galvanic current of from five to fifteen, or even twenty, milliampères, according to the seat of the stricture, the nature of the neoplasm, the size of the electrode, and other conditions. The seances are of from five to fifteen minutes, and under some circumstances thirty minutes, and are repeated in one or two weeks. No force should be used. The electrode should be kept steadily against the stricture and only guided until the electrolytic action does the work of enlarging the calibre and the instrument passes the obstruction.

It seems that females are more inclined to have rectal stricture, as out of the twelve only two were males. Their ages were mostly between thirty and forty; the youngest was twenty-four, the oldest sixty-two years of age. The two males were comparatively young men, twenty-three and twenty-six years of age. Eight cases were single strictures, and four had multiple strictures. The duration of the malady was from six months to twenty years. The causes varied, but hemorrhoids and constipation were important factors; other causes were syphilis, venereal enteritis, and dysentery. It is believed that rectal stricture may follow any inflammation of the rectum. One case was complicated by five fistulæ, which healed without further treatment after the stricture had been cured. Eight cases had had previous treatment; of these, six had had operations with the knife. In none had the previous treatment been successful. Of the twelve cases reported, nine are claimed to be cured, and three temporarily improved. The nine cured cases had shown no relapse during the time they were under observation—from one to ten years. Other successful cases were referred to, treated by Dr. Samuel Benton and Dr. W. T. Whitmore, of London, and Dr. S. T. Earle, of Baltimore.

The conclusions drawn were as follows:

Electrolysis in the treatment of stricture of the rectum is not a panacea; failures may occur, and may be expected if the stricture be due to carcinoma.

Electrolysis will give improvement to rectal strictures when other means have failed.

Electrolysis will cure a certain percentage of cases, without a relapse, better than other modes of treatment, and without the necessity of using bougies or any after-treatment.

The best chances for a cure are with the fibrous inflammatory strictures. The best mode of treatment is by a metallic bulb as negative pole, with weak currents at intervals of four days to two weeks.

---

FOURTH DAY, FRIDAY, JUNE 28TH.

DR. FRANK WOODBURY, of Philadelphia, presented a new model inhaler for administering ether or chloroform, made by E. A. Yarnall, of Philadelphia, in which the anæsthetic is dropped into a funnel-shaped opening at the top and falls upon absorbent cotton confined in a chamber beneath, where it is confined by a perforated, hinged diaphragm. The advantages are cleanliness, convenience, and cheapness.

DR. CHARLES DENISON, of Denver, Col., exhibited

A NEW RIB CUTTER,

and narrated

A CASE OF RESECTION OF RIBS FOR DRAINAGE OF A PULMONARY CAVITY.

The lung-cavity was treated by washing out with antiseptic solutions. The case terminated favorably. The rib-cutter was devised with the end in view to make as small an opening as possible, and to leave the periosteum intact.

DRS. W. BARTON HOPKINS and C. B. PENROSE, of Philadelphia, read a paper on the

ORGANIZATION AND ABSORPTION OF STERILIZED DEAD-BONE DOWELS,

in which were shown the effects of retaining for various periods ox-bone dowels in contact with living bone. The experiments were performed upon dogs, and demonstrated that organization of the dead bone, as evidenced by the presence of blood-vessels continuous with and extending from the living bone, readily occurs. After five weeks bone dowels lose their power to give support to fragments or extremities of bone in which they have been introduced, begin to undergo absorption in the medullary cavity, and active organization in the shaft of the bone.

From these experiments we base the following deductions:

1. That when sterilized dead bone is placed, under favorable circumstances, in contact with living bone, it undergoes organization. When, on the other hand, it is acted upon by periosteum it is absorbed, and when placed in the medullary cavity, in not too large bulk, organization, combined with absorption, takes place.

2. That these processes go on perhaps most actively between the fifth and eighth week, and are not necessarily associated with any inflammatory action.

3. That, therefore, where these dowels are employed to pin together fragments of bone after fracture, to fix the extremities of bone after resections, or for any other mechanical purpose in surgery to which they are adapted, they may be relied upon to do their work for a period of one month or six weeks, and hence to give ample time, as a rule, for union to occur. After this, their presence being no longer required, they gradually lose their identity in surrounding bone, and disappear.

DR. CHARLES DENISON, of Denver, Col., presented

A CASE ILLUSTRATING THE DRAINAGE OF A PULMONARY CAVITY.

The case, taken from the writer's records, was that of a man, twenty-six years of age, first examined, November 3, 1888. The previous April he had had a pneumonia of

the left lung, and softening was determined to be present in the left axillary space. Though his stay in Colorado was accompanied with increased weight and strength, yet the signs of tubercular infection and breaking down of the living tissue continued, as shown by the afternoon-hectic and the daily expectoration of half a pint of purulent sputa, night-sweats, etc. January 14, 1889, pulse, 110; respiration, 40; temperature, 101⅓° F. at 2 P.M.

Permanent drainage was advised, and the operation performed on January 22d; portions of the sixth and seventh ribs were resected. A new treatment of the cavity was devised: that of daily injection of a ten per cent. solution of salol in liquid vaseline. This was carried out by the patient, as well as the antiseptic cleansing of the cavity.

March 16th, pulse, 92; respiration, 28; temperature, 98⅘° F. at 4 P.M.; weight increased thirteen and a half pounds since the operation. Discharge from the tube reduced to one ounce a day, and expectoration as well as cough had ceased since the operation. Symptoms all improved.

On May 10th the drainage-tube was shortened from four and a half to three and a half inches, and it lay along the bottom of the pulmonary cavity, which was one and a quarter by three and a half inches in size, extending along the left side of the sternum, from the clavicle downward and outward toward the left nipple, being situated beneath the front wall of the chest. Air was then found to enter around the cavity, above and outwardly. No fever; and arrest of lung disease assured. Since then the patient has done well.

The rib-cutter, suggested to the writer by the difficulty of resecting the ribs because of their overlapping in this case, was presented. It is composed of a periosteum separator, curved at the point, upon which a sliding, cutting blade is forced by a toggle-joint which gives the operator great power in making a clean, even section of the bone. This was illustrated in a satisfactory manner to those present. By this instrument a portion of a rib can be first denuded of its periosteum, and then one and a third inch, or more, of it can be excised, and removed through an external opening only large enough to admit the instrument, *i. e.*, one and a quarter inch long.

DR. J. G. CARPENTER, of Stanford, Ky., read an exhaustive paper on the

PATHOLOGY AND TREATMENT OF CHRONIC SCIATICA,

and reports two cases of operative nerve-stretching.

The first patient had chronic sciatica of the right nerve. The trunk was inclined to the left; the vertebral column described a curve with its convexity to the right; the left hand descended much lower than the right; the right lower extremity was semi-flexed; the buttock of this side presented a flattened appearance, the gluteal fold being elevated; finally, the heel of the right foot did not touch the floor. The limb was atrophied and cold, one and one-half inch smaller from the hip to the foot than the left, and the patient was unable to sit on the right buttock. The condition of the nerve on exposure, before stretching, was this: The neurilemma was found to be thickened, congested, and numerous reticulations of small blood-vessels ramifying the sheath. The latter had lost its opacity and was a pinkish, yellow color, had many nodular deposits, and many adhesions to the adjacent tissues, showing plainly that the case was one chronic sciatic perineuritis.

Attitude of second case, left sciatic nerve being affected: Trunk inclined to the right; the vertebral column curved to the left, when the pain was great; the left lower extremity partly flexed, except when walking on the street; the left buttock flattened, and the gluteal fold elevated; and the heel of the affected side can be made to touch the ground only with pain. In the recumbent posture the left limb was flexed, and pads or pillows had to be placed under the knee and back to remove pressure from the tender points; otherwise the patient could not lay on the back or left side. The limb was one and one-half inch smaller from hip to foot than the right, and cold and atrophied; the patient could not sit on the left thigh and buttock. On cutting down there was found to be some fibro-cystic tumors and nodular deposits on the nerve (perineuritis nodosa chronica), and bands of lymph and adhesions between the sheath and adjacent tissue. The neurilemma had lost its normal appearance and showed signs of fatty degeneration, and was traversed by many small blood-vessels.

DR. J. WILLIAM WHITE presented a communication on

THE SURGERY OF THE SPINE.

Dr. White divides the spinal troubles which may necessitate surgical interference into three classes: traumatisms, caries, and neoplasms. He reviewed the history of the surgery of these conditions, gave the details of two cases in which he performed resection of the spine, and reached the following conclusions:

1. The objections urged against operative interference in spinal traumatisms were partly theoretical (hemorrhage, frequency of absolute destruction of the cord, pressure from inaccessible fragments of bone, etc.), and have been shown to be unsupported by clinical facts. They were largely due to a well-founded dread of (*a*) the shock, in the cases operated on in pre-anæsthetic times; and (*b*) consecutive inflammation, suppuration, and pyæmia in pre-antiseptic periods. The later results, which now constitute our only safe basis for generalization, are distinctly encouraging, and resection of portions of the vertebræ in fractures, possibly even in dislocations, should be recognized as an eminently proper operation and, in suitable cases, altogether warranted by the facts in our possession; and further, such cases are by no means rare or exceptional.

2. There can be still less doubt that the testimony of both pathologists and practical surgeons indicates that the cause of the paralysis of Pott's disease is, in many instances, an extra-medullary proliferation of connective tissue, assuming the density and proportion of a neoplasm, occupying the space between the dura and the interior surface of the laminæ, not apt to be associated with intra-medullary changes or with destructive degeneration of the cord, and very frequently removable by operation.

3. Every case of focal spinal lesion, thought to depend on a tumor, and not distinctly a malignant and generalized disease, should be regarded as amenable to operative interference, no matter how marked the symptoms of pressure may be, nor how long continued.

4. The method of extension, as recently revived, is well worthy of preliminary trial in the first two classes, and in obscure cases thought to belong to the third class. It has not yet been tried in a sufficiently large number of cases to establish its exact limitation, but it is unquestionably a therapeutic measure of vast importance in spinal injury and disease.

It is customary and proper, in deciding upon any serious surgical procedure involving risk to life, to consider well the prospects of the patient in the event of non-interference, and to be largely influenced by them. Looked at in this light, the operative surgery of the spine as regards traumatisms, caries, and neoplasms may fairly be said to have a rapidly widening field, and to deserve more serious and careful consideration by practical surgeons than it has received for many years.

The following papers were read by title: "The Surgery of the Lateral Ventricles of the Brain," by W. W. Keen, of Philadelphia; "Arthrectomy of Knee-joint," by E. H. Bradford, of Boston; "Epicystic Surgical Fistula for Relief of Vesical Catarrh," by J. D. S. Davis, of Birmingham, Ala.; "Drainage in Abdominal Surgery," by Charles B. Penrose, of Philadelphia; "A Plea for Early Abdominal Work," by M. Price, of Philadelphia; "Wiring the Patella in Old Ununited Fracture," by W. C. Wile, Danbury, Ct.; "The After-treatment in Cases of Abdominal Section," by L. S. McMurtry, of Louisville; "Cranial Surgery," by H. O. Walker, of Detroit; "Fis-

tula in Ano," by J. M. Mathews, of Louisville; "The New Improved Aseptic Surgical Pump," by Elmer Lee, of St. Louis; "Incomplete Inward Dislocation of the Radius and Ulna of the Elbow," by Albert Stifel, of Wheeling, West Va.

## SECTION ON DISEASES OF CHILDREN.

### THIRD DAY, THURSDAY, JUNE 27TH.

A PAPER by Dr. Marcus P. Hatfield, of Chicago, on "The Value of Hydrogen Dioxide in the Treatment of Children," was read by title. A paper by Dr. David S. Booth, of Sparta, Ill., on "Penal Rule in Public Schools," was read by title.

DR. S. P. DEOHOFE, of Potsdam, O., read a paper on

#### POLIO-MYELITIS ANTERIOR ACUTA.

The author related the histories of five cases he had seen. He thought the diagnosis not always easy. He believed that in treatment the effects of electricity are not brilliant. The first treatment should be always rest.

DR. KING, of Chicago, had seen three cases in adults. Pain was a symptom in adults, but was not found so readily in children. In his experience the bladder was always paralyzed, but was all right at the end of two or three days. In one of his cases the atrophy was extreme at the end of three weeks. Considered electricity harmful in the early stages.

THE CHAIRMAN thought that electricity never did good.

DR. HOOPER agreed with the Chairman.

DR. I. N. LOVE, of St. Louis, read a paper entitled

#### ONE YEAR OF ACETANELIDE IN PÆDIATRIC PRACTICE.

The author stated that he considered acetanelide superior to any of the carbolic-acid series. He believed it better to use the name given at the head of the paper in preference to the patented one of "antifebrin." He regarded the drug as three times more effective than antipyrin and less depressing. If it diminished the red blood-cells, it required a long administration to do so. The depressing effects resulted from poor makes of the drug. He agreed with Widowitz in his view of the safe and steady action with children. He did not believe the disagreeable cyanosis was of special importance, and it could be overcome by combining with alcohol. He made mention of the advantage of the use of the drug in scarlet fever, measles, and congestive fevers. The author spoke of the treatment of fifty cases of whooping-cough by acetanelide, and thought it a valuable remedy. In conclusion the writer of the paper stated the following: Acetanelide, carefully guarded and properly used, is a safe and reliable remedy in the diseases of infancy and childhood. It is preferable to antipyrin, because it does not cause so much depression, and its effects last longer. The cyanosis is not a dangerous, though it is a disagreeable, feature. It is of value in controlling temperature in fever caused by the typhoid germ. It serves almost as a specific in whooping-cough, by mitigating the discomforts and controlling the paroxysms of the disease.

DR. DIXON, of Kentucky, did not think the acetanelide equal to antipyrin, except as a febrifuge. Had had alarming effects following its use. In malarial fevers gave it, and followed it with quinine.

DR. HILL, of New Hampshire, gave eight- or ten-grain doses in asthma.

DR. KING, of Chicago, had seen relief by twenty-grain doses in a case of cerebral tumor.

DR. W. P. WATSON, of Jersey City, did not advise its use in self-limited fevers.

DR. ATKINSON, of Baltimore, had not seen the impure drug. Did not think we could modify fever, but could contribute to the comfort of the patient.

THE CHAIRMAN advised the use of the drug in hyperpyrexia with pale skin, to dilate the capillaries.

DR. OSLER, of Baltimore, had given acetanelide in the cold stage of fever, but had found it useless.

DR. WOODBURY, of Philadelphia, did not believe in prescribing patented drugs, and therefore did not use it.

DR. LOVE, in closing the discussion, reiterated that the cyanosis was not dangerous, but the drug could be combined with alcohol.

Dr. J. C. Wilson, of Philadelphia, read by title a paper on "Visceral Neuralgias in Children."

DR. WILLIAM P. WATSON, of Jersey City, read a paper entitled

#### ATROPINE IN ENURESIS.

The author had treated thirty cases by atropine, and cured twenty-seven. He gave one drop, for each year of the child's age, of a solution made by adding one grain of atropine to one ounce of water.

The paper was discussed by DRS. DIXON, LARRABEE, HILL, JEFFRIES, and KNAPP.

Dr. William Osler, of Baltimore, read by title a paper on "A Further Study of the Cardiac Relations of Chorea."

The following papers were read by title: "Adherent Præputium Clitoridis as a Cause of Chorea, with Report of a Case," by C. Henri Leonard, M.D., Detroit; "The Treatment of Heart Disease in Children," by J. A. Robinson, M.D., Chicago; "The Physical Education of Children," by H. P. Leuf, M.D., Philadelphia; "The Treatment of Tubercular Bone Lesions before the Joint is Invaded," by V. P. Gibney, M.D., New York; "Notes on Surgical Diseases of Children," by Edward Brock, M.D., St. Louis; "Spina Bifida," by Norman Teal, M.D., Kendallsville, Md.; "Trismus Nascentium," by A. V. Williams, M.D., Frankfort, Ky.

## SECTION IN DERMATOLOGY AND SYPHILOGRAPHY.

### THIRD DAY, THURSDAY, JUNE 27TH.

DR. HENRY FLEISCHNER, of New Haven, read a paper on

#### PRURITUS.

The author described in an interesting manner the clinical difference between the pain of pruritus and ordinary pain, and mentioned the many unsettled questions connected with etiology, pathology, and therapy. The treatment had to be adapted to the individual case, was largely empirical, and when successful proved so by accident. He had most frequently found menthol useful. Results from electricity he thought were largely imaginary. Acetic acid had been of value in many cases, also resorcin and kairin. Results from sulfonal had not encouraged him to continue its use.

DR. CORLETT had obtained most benefit, according to the class of cases, from tepid baths, menthol ointment or solution in alcohol, carbolic acid, and tar applications.

#### CLINICAL STUDY OF ECZEMA SEBORRHOICUM.

The paper was sent by DR. GEORGE T. ELLIOT, of New York, and was based on the observation of 208 cases the past eighteen months. They constituted twenty-nine per cent. of all cases of eczema seen during that time. Thirty-six of the cases were seen during the three summer months. Of the 208 cases 134 were in females. All ages were affected. The majority of cases occurred between the tenth and thirteenth year. The scalp was affected in all the cases. In 118 the eruption was limited to the head and face. The progress of the eruption was slow. The author thought it was a purely local affection, not being affected by constitutional conditions or treatment. In only a few cases was itching severe. Some patients stated that the eczema had been present even as long as ten years, perhaps changing location. The scale was unusually branny, the area of red or yellow, bare, greasy, from size of a pea up. The skin between the patches might be normal, greasy, or covered with scales.

DR. BULKLEY did not believe as large a proportion of cases of eczema fell under the division of eczema seborrhoicum as appeared from Dr. Elliot's paper; that other

forms of eczema had been confounded with this late division made by Una. He also differed from the author in the view that it was purely local, requiring only local treatment.

Dr. Corlett expressed essentially the same views entertained by Dr. Bulkley, and said the subdivision made by Una was accepted with more or less reserve in Paris, Vienna, Berlin, and London.

Dr. J. Abbott Cantrell, of Philadelphia, reported a case of

PAINFUL SUBCUTANEOUS NEUROMA.

It occurred in a man, aged twenty-eight, the tumor beginning to grow in the region of the deltoid fourteen years ago. Others had appeared since, and numbered about six, on either arm, in the same region. The largest was of the size of a pea. At first they caused itching, afterward they became painful, the pain being paroxysmal, and excited especially by contact of clothing and blows. It was at times extreme, and like the cutting of a knife. He had been disappointed in exsecting a tumor for examination, but presumed it to be neuro-fibroma.

Dr. Louis Wickham, of Paris, sent a paper entitled

NOTES ON THE PARASITIC THEORY OF ALOPECIA AREATA.

So long, he said, as a specific parasite for this affection was not found and proven beyond doubt, the parasitic theory would encounter many adversaries. But in favor of this theory, in default of discovery of the parasite, there were facts of contagion which seemed clearly proven. In the Hospital St. Louis they had met with different ways of transmission of variable importance. For instance (1) a small girl affected with alopecia, a sister sleeping in the same bed was frequently attacked with the same affection. (2) Three children of the same family had taken alopecia at short intervals from each other. (3) A small girl coming from the country to stay with relatives where a child has alopecia, one month later shows plaques of alopecia. (4) A young man had alopecia over the right temple, a place which was rubbed by the rim of his helmet. He had worn about two months the helmet of a friend who had alopecia. The plaque corresponded exactly to the part rubbed by the helmet. (5) Four men working together in a small room were affected, one after the other, within some months, with plaques of alopecia. They sought advice how to protect their fellow-workmen from the disease, which they were convinced was contagious. They frequently exchanged hats, which doubtless served as agents of transmission. There were other striking examples of contagion in French medical literature.

The author was far from denying the existence of an alopecia of neurotic origin, but the facts given, which came under his own observation, and others quoted, proved, he thought, the existence of a contagious form. Some objections to the theory were discussed. They were alike applicable to most diseases known to be contagious, but in which the parasite had not yet been discovered.

The following papers were read by title: "Eruption produced by Internal Use of Rhubarb," by Dr. H. Goldenburg, New York; "General Points in the Treatment of Inflammatory Diseases of the Skin," by Dr. Oscar Lassar, Berlin.

---

## SECTION ON LARYNGOLOGY AND OTOLOGY.

First Day, Tuesday, June 25th.

W. H. Daly, M.D., Chairman.

Dr. John O. Roe, of Rochester, N. Y., read a paper on

GLANDULAR HYPERTROPHY AT THE BASE OF THE TONGUE, AND ITS TREATMENT.

Until recently the importance of this condition was not recognized. He referred to it under the usual name of "lingual tonsil." The lingual and the faucial and pharyngeal tonsils are the same in structure and function—their chief function being the secretion of mucus. The lingual tonsil is liable, from its position, to irritation by the passage of food, etc. and the blood-vessels in and about them seem subject to all the variations of the temperature of solids and liquids which pass over them, and very naturally the glands frequently take on an abnormal condition as a consequence. An abnormally distended condition of the blood-vessels is found in these hypertrophies. These vary according to the conditions of local irritability, but also with the plethoric condition of the general system, and may, as Mr. Lenox Brown has pointed out, be symptomatic of mitral disease or hepatic engorgement, or even cerebral tumors. Small ruptures over these glands may be the origin of blood-spitting. They are often associated with the same condition of the other tonsils, and the symptoms often resemble those of hypertrophy of the faucial tonsils, causing changes in the voice and inarticulation, and the sensation of a foreign body in the throat, as of a hair, etc. Attacks of asthma are not infrequent from this cause, and globus hystericus is often observed in this association in females.

Diagnosis is easily made by inspection on drawing the tongue forward.

Treatment has two objects to accomplish: 1, removal of all hypertrophies; and 2, obliteration of all varicosed blood-vessels. The first is best accomplished by abscissions with a curved knife or scissors, is easily done, and unattended by much hemorrhage or soreness. The galvanic cautery is also useful. Corrosive substances are also recommended, as chromic and nitric acid, Vienna paste, etc. In cases of moderate enlargement, caustics may prove efficient. In using the galvano-cautery the hypertrophy may be burned away by a flat cautery, applied from the summit downward, by cutting off at the base with the cautery knife, or by transfixing through the base with a very slender cautery point. For destroying the enlarged vessels the last instrument should be used, applied longitudinally to the trunk of the vessel at the point from which they arise, as near as possible. Before any of these operations cocaine should be applied.

Dr. Solis-Cohen objected to the term "tonsil" applied to collections of lymphoid tissue, other than those existing between the arches of the palate. He approved of the author's method of getting rid of the growths. In case of slight enlargement he found that a solution of creosote, or carbolic acid and iodine in glycerine, sufficient topical treatment.

ELECTION OF OFFICERS.

Dr. John O. Roe, of Rochester, N. Y., was elected President, and Dr. Frank H. Potter, of Buffalo, N. Y., Secretary.

Dr. E. Fletcher Ingalls, of Chicago, read a paper on

ELECTROLYTIC TREATMENT OF CYSTIC GOITRE.

The author referred to the various conventional methods of treatment, and especially to that of Sir Morell Mackenzie, first published in 1872, and which is pronounced in Holmes' "System of Surgery" to be the most efficient. This consists of injecting into the cyst a solution of perchloride of iron, and allowing the cannula of the trocar, tightly plugged, to remain in place for three days. If, on removing it, suppuration does not take place, the same procedure is repeated, this being followed by poulticing.

The author claims for electrolysis that it produces more rapid results, is less dangerous, and has other advantages over other methods, and gave the history of two cases in support of his views, which had been treated by him by electrolysis.

In the first case, after several tappings, followed each time by rapid reaccumulation of fluid, electrolysis was used, and after three or four applications, for ten minutes, of from six to ten Leclanche cells, the cysts ceased to refill, and remained cured. The tumor had been found to be about one-third solid tissue. This remained, but

did not increase. A needle was passed into the cyst and the other pole of the battery applied over the tumor.

The second case was one which had existed for several years, and had been injected with iodine and other fluid but continued to remain of about the same size. Electrolysis was first employed on February 23d, and after four or five applications, on March 23d, it had ceased to refill and the cyst was completely eradicated. The strength of the current was regulated by the patient's ability to bear it.

Dr. D. Bryson Delavan, of New York, then read a paper on

ADENOID HYPERTROPHY OF THE VAULT OF THE PHARYNX; ITS PATHOLOGY AND TREATMENT.

The author stated that there were two principal varieties of the disease. In one the growth was soft, friable, and rich in lymphoid elements; in the other there was an excess of fibrous tissue. The first was removable with ease and little pain—the other was exceedingly tough and removal caused much pain. The methods of operation were alluded to, and it was insisted that in the more severe cases, even in young adults, the use of anæsthetics is of the greatest importance and that removal should be completed if possible at one operation. The author also insisted upon the great importance of the proper after-care of patients thus operated upon, and recommended that they be put upon a course of tonic treatment, and that the mouth-breathing habit be corrected by special attention thereto; that deformity of the chest, if present, be remedied by proper physical exercise, and finally, that errors of pronunciation be eradicated. The paper was illustrated by numerous instruments and by several fine colored drawings.

Dr. Lawrence Turnbull, of Philadelphia, then read a paper on

THE VALUE OF ANTISEPTIC TREATMENT AND PROTECTION OF THE MEMBRANA TYMPANI IN PERFORATIONS THE RESULT OF OTORRHŒA.

He stated that it was not necessary to dwell upon the absolute importance of antiseptic surgery. Its latest and most brilliant results have lately been seen in brain surgery. It is not only possible to reach and drain abscesses in the temporo-sphenoidal lobe of the cerebrum, but it is considered possible to save life by opening into the cerebellar fossæ and remove pus from the neighborhood of the lateral sinus. The antiseptic treatment of chronic purulent disease of the middle ear was a natural sequence, and was soon followed by the use of boracic acid in powder and solution, later by bichloride of mercury, alone and in combination, then by the use of antiseptic wool and gauze, with the protecting agency of oil-silk, which protectors act as artificial membranes and prevent the entrance of disease-germs from the air.

The author then referred to the various causes preventing the cure of chronic discharge from the ear, also the treatment of perforations of the membrana tympani by means of grafts of skin, lining membrane of the chicken's egg, skin of the frog's foot, and nictitating membrane of the frog's foot. The paper concluded by reporting a few cases in illustration of the subject.

Dr. F. H. Potter, of Buffalo, N. Y., then read a paper on

THE USE OF MENTHOL IN THE UPPER AIR-PASSAGES,

with the results of its use by him during the past three years by local application. These results indicate that the drug controls superficial inflammation; that it is an analgesic, and second application can be made in increasing strength without discomfort; that it is destructive of some of the low forms of life, especially the bacillus tuberculosis, and that it is a valuable antiseptic in nasal surgery. It has an important place in the treatment of atrophic conditions. It can be used in strength of from one to fifty per cent. dissolved in oil. The oleum petrolia the author considers the best for the purpose of dissolving the drug. It can be applied directly by cotton application, or by means of the spray or by vaporization. The direct method answers best in the pharynx, the spray and vapor for the nose and larynx. Five cases of laryngeal phthisis following upon disease of the lungs were also reported, in which the menthol treatment gave satisfactory results, the local conditions improving rapidly under its use.

Dr. Charles H. Knight, of New York, read a paper on

MENTHOL IN LARYNGEAL PHTHISIS.

Twenty cases, most of them of a severe type, treated with menthol applications, furnished the author ground for believing that this is a valuable agent in tubercular laryngitis. The drug was dissolved in fluid cosmolene in the proportion of a drachm or a drachm and a half to the ounce, and applied by means of a laryngeal syringe, or in the form of spray, by a nebulizer or vaporizer. In nearly all cases the subjective symptoms and the local appearance improved. In no case did complete healing of an ulcer take place. In this respect the author's experience does not bear out the representations of Rosenberg and others. Three propositions are offered: (1) Spontaneous cure of a tubercular ulcer of the larynx may occur; (2) a simple erosion or ulceration may be mistaken for a tubercular ulcer; (3) the best results from local treatment of the larynx may be expected in cases of incipient or limited pulmonary disease and in primary laryngeal tuberculosis.

Dr. H. Holbrook Curtis, of N. Y., then read a paper entitled

ANÆMIA AND ITS RELATION TO NASAL STENOSIS.

By a tabulation of cases he demonstrated that nearly all patients with stenosis were anæmic, the percentage of oxyhæmoglobin being only about one-half that of normal blood. In his experiments he had used the hæmatoscope of Hénocque, and had again tested the blood after several weeks had elapsed. The conclusions arrived at were that the increase of oxyhæmoglobin in the blood after operation on the septum is directly proportional to the relief afforded an impeded nasal respiration. This increase is constant, and averages about two per cent. in the six weeks immediately following operation, in which the stenosis is about fifty per cent., or in which the nose is doing one-half its work.

Cases should not be operated on whose blood shows by spectrum analysis less than six per cent. of oxyhæmoglobin, as profound hæmorrhage is apt to occur. Records had also been kept in regard to body weight, chest measurements, and capacity of the lungs by the spirometer. These factors also exhibit improvement after operation.

Dr. F. S. Crossfield, of Hartford, Conn., read a paper on

EPILEPSY CAUSED BY INTRANASAL DISEASE.

The author stated that the first case that came under his notice, in 1886, had all the appearance of some grave lesion of the lungs — emaciation, hacking cough, more severe at night, headache, night-sweats, and anorexia. Had epileptic convulsions, the first six years, twice a month, or oftener. Associated with this condition was marked nasal hypertrophy of both cavities, with deflected septum to left side, and exostosis, whose sharp angle pressed against the hypertrophied turbinated body; marked adenoid growth of the naso-pharynx; slight changes in the larynx. Epilepsy entirely disappeared when this pathological cause was removed, and the patient is now entirely well.

The second case was much like the first, only with slight enlargement of the pharyngeal tonsil. The epileptic seizures were much more frequent. This case likewise fully recovered on removal of the local cause.

Dr. J. G. Carpenter, of Stanford, Ky., read a paper entitled

INTERNAL EAR DEAFNESS.

The author said that many of the cases of internal ear deafness were due to nasal disease, and by curing the

latter the former is relieved. Nasal disease should be treated before structural lesions have taken place in the internal ear. Two cases were reported in illustration of his subject by the author.

DR. J. A. LIPPINCOTT, of Pittsburg, Pa., reported a case of

SCLEROSING MASTOIDITIS,

occurring subsequently to primary purulent mastoiditis interna; opening of mastoid; exposure of dura mater; recovery.

In September, 1885, the mastoid had been opened by another surgeon, and an abscess found and carefully cleansed. The wound had healed, and severe pain was relieved for six months, when it recurred, gradually becoming very severe, until July, 1886, when it came under the author's observation. Other measures failing, in October a considerable opening was made in the mastoid, which accomplished nothing, immediately. The condition became more and more serious. Convulsions finally set in. In May, 1887, a second operation was performed with the intention of making the opening sufficiently large and deep to give relief. In this attempt the dura mater was exposed to the extent of one-fourth of an inch in diameter at the bottom of the wound. The pain disappeared immediately. Convalescence was rapid. An examination a few days ago showed exemption from pain. Extreme pain had been the chief symptom, there having been no inflammatory appearances about the ear or the mastoid region. The patient was a young woman.

---

THIRD DAY, THURSDAY, JUNE 27TH.

DR. D. N. RANKIN, of Pittsburg, Pa., read a paper entitled

EFFECTS OF NATURAL GAS UPON THE UPPER AIR-PASSAGES.

Natural gas was introduced to use in Pittsburg in 1883. It at first gave rise to great complaints. It made the air too dry to breathe; it ruined furniture by cracking the joints; it was repudiated by many who had tried it, and the apparatus for its use removed from their dwellings. Explosions also occurred. But it is a very cheap fuel and light, and experience taught how to use it without producing these effects. Chemical analysis shows it noxious to breathe. The pipes were at first made of too porous metal and leaked; now it is used without these defects, and is no longer breathed by the users, and no deleterious effects are produced upon them.

Patients suffering from its inhalation will complain at first of dryness of the throat and nares. This is followed by free discharge of naso-purulent matter from these cavities. After this the dryness recurs, sometimes the symptoms extending to the larynx and producing hoarseness. Mirror examination shows congestion in the nose and pharynx, and great sensibility exists in these parts, promptly relieved by a four per cent. solution of cocaine, followed by vaseline to the nose and throat.

DR. GEORGE A. RICHARDS, of New York, read a paper on

EMPYEMA OF THE FRONTAL SINUSES.

The author reports a case of empyema of the frontal sinuses due to obliteration of the infundibulum by a polypi which had existed fifteen years. The empyema had produced absorption of the lower wall of the sinus, and a small tumor had appeared at the root of the nose about eight months before the patient presented himself for treatment. An opening was made into the swelling, and a tube passed through into the nose, after about twenty polypi had first been removed. After thorough cleansing thrice daily for about a month, the patient completely recovered. Sight improved at once, and complete relief to a very marked anorexia, and great improvement in the general health as well as in breathing and smell.

Of forty-eight cases collected by the author from literature, only fourteen were the result of injury, and but seven the result of obstruction. Some cases occur many years after injury. The majority occur without known cause. The symptoms are more or less those of an ordinary coryza, together with a feeling of distention, exophthalmus, diplopia, failure of eyesight, and the appearance of a tumor over the superciliary ridge or at the root of the nose; hard at first, this soon becomes soft and fluctuating.

The only treatment is to make an extensive opening into the nose through which a perforated rubber tube should be passed. Cleanliness and free drainage are most important. Of twenty-five cases so treated cure resulted in twenty-three; in two result was not stated; while when drainage into the nose was neglected the results were not nearly so good. Death occurred in six cases; in four from secondary cerebral abscess; in one from meningitis, and in one from albuminuria.

DR. C. W. RICHARDSON, of Washington, D. C., read a paper on

POSSIBLE DANGER OF INJURY TO THE MIDDLE EAR BY THE USE OF NASAL ATOMIZATION.

The author anticipated criticism as to the reality of such dangers being very great. He wished especially to call attention to the danger to the middle ear from the use of such spray instruments as Davidson's and Snowdon's atomizing tubes because of the direct pressure exerted. The first case was that of a lady. The author was spraying the nose to remove crusts with Dobell's solution. An acute pain was experienced in the ear; spray was cut off at once. This was followed in a few hours with typical acute middle-ear inflammation. The other two cases were similar ones.

The author thought it a common experience with rhinologists in spraying the nose to have the patient remark that he felt the spray go into his ear. He did not wish to decry the spray, a very useful means of treatment, but simply to point to the possible danger it involved and to caution against the indiscriminate prescribing hand-sprays to be used by the patient upon himself.

DR. JOSEPH A. WHITE, of Richmond, Va., read a paper entitled

THE SO-CALLED THIRD TONSIL.

The author believed that glandular hypertrophy in the post-nasal space, even when slight, is an active agent in keeping up a catarrhal condition of these and neighboring parts, and causing extension to the ear. To get rid of the catarrhal condition these growths must first be destroyed—the same treatment must be applied also to removal of the faucial tonsils for the same reason. We do not know the exact function of these tonsillar tissues, but we do know that their removal does no harm. Perhaps the third tonsil plays a greater part in the production of secondary disease than the faucial, and this is easily understood when their relation to obstructed respiration and ventilation of the Eustachian cavity is considered. Marked impairment is present in these cases.

Besides the mulberry-like growths there may be round projections or conical ones, or several knob-like swellings, or flat, cushion-like masses, etc. These growths are sometimes soft and easily removed, at others compact and tough, and hard to get rid of. The Eustachian tubes are apt to be especially infringed upon by the latter, from pressure. Statistics are unreliable, because careful examination and noting as to deafness is not often made by rhinologists. There is always more or less deafness where these growths exist. Out of 565 cases of private practice in eighteen months of naso pharyngeal affections, the author had found 197 had disease of the middle ear. Of these 134 had hypertrophy of the third tonsil—twenty per cent. of the whole number treated.

An interesting point is the large number of voice defects in these cases. This is scarcely understood, knowing as we do, in our experience with professional singers and others who habitually use the voice, the necessity of perfectly clear

arching of the naso-pharynx to secure perfect resonance and timbre.

The presence of these growths causes an increase of catarrhal secretion which can only be removed by eradication of the hypertrophies—the only local means which proves effective in treating the catarrh. Neglect of this may lead to more serious troubles; for example, anterior turbinated hypertrophy; another is the occasional paralysis of the alæ of the nose, causing serious impediment to breathing.

The method of removal is unimportant, provided it is thorough. Large masses are best removed with the galvano-cautery snare or cutting forceps, the latter is painful even with cocaine anæsthesia. Galvano-cautery points are best, perhaps, for soft, smooth masses.

The author had found his palate-retractor of great help in these operations. The paper was illustrated by reports of cases.

Dr. W. K. Simpson, of New York, reported a case of

ACUTE RHEUMATIC LARYNGITIS OF GONORRHŒAL ORIGIN.

The author remarked upon the extreme rarity of the case, not having been able to find reference to a similar one. Seen first on February 23, 1888. The patient gave the history of previous attacks of gonorrhœa, the present attack being of five weeks' duration. The rheumatic pains and stiffness had existed three weeks in both knees and hips, for three days in left thumb and wrist, presenting at this time typical swelling of acute rheumatism. Laryngeal symptoms began three days ago, with painful deglutition. On the following day there was a painful swelling of the lower external portion of the larynx. In the evening the patient became very hoarse, and talking was very painful. February 23d, examination of the throat revealed painful deglutition, pain on pressure over right side of larynx, and absence of cough. Internally, both arytenoids swollen and red, right much in excess, and somewhat œdematous; the right vocal cord immobile on phonation, all of interior of the larynx more or less hyperæmic, the right vocal cord being of a deep purple color and considerably swollen. The treatment consisted of the use of salicylic acid, which did not prove entirely effective. Laryngeal swelling increased, embarrassing respiration. On February 29th a blister was applied to external larynx, and iodide of potash administered. On March 6th he had greatly improved, but there still remained little motion of the right arytenoid and cord, and they were both still very red.

Dr. A. B. Thrasher, of Cincinnati, O, read a paper on

MORBID PERFORATIONS OF THE NASAL SEPTUM.

The author reported sixteen cases of morbid perforation of the septum narium, having special reference to the syphilitic theory of the origin of the disease. Three of the cases occurred in syphilitics, eleven where syphilis had not been present, and two cases were doubtful. In syphilitic cases the vomer, or at least one of the turbinates, was invariably attacked, and pain was always felt when this was the case. In the non-syphilitic cases the perforation, as a rule, gave rise to no symptoms; at times it seemed to have been caused by picking the nose with the finger-nail. There was localized anæsthesia in the ulcerated area. The application of the galvano-cautery produced no pain. The treatment consisted locally in detergents, caustics to the ulcerated area, and mild ointments; and internal remedies addressed to the underlying dyscrasia.

Dr. J. E. Schadle, of St. Paul, Minn., read a paper on

COUGH IN ITS RELATIONS TO MORBID STATES OF THE NASAL PASSAGES.

The symptomatology of morbid processes seldom furnish a more perplexing subject for analysis as to its primary cause than that of cough. A chronic cough which does not yield to ordinary treatment, and whose origin is obscure, is apt to excite extreme anxiety in the sufferer. The subject is interesting from its practical relations.

Three cases were reported, in which chronic cough of long standing was cured by directing proper measures of treatment to removal of existing nasal disease, consisting in one of posterior hypertrophies of the inferior turbinated bodies; another, of nasal stenosis caused by deformity of the nasal septum; and a third, of chronic nasal catarrh.

The author maintained that when cough is thus pathologically connected with morbid states of the nasal passages it is usually produced by reflex nervous influences or paresis of the vaso-motor blood-vessels of the intranasal mucous membrane.

Dr. Charles Denison, of Denver, Col., read a paper entitled

A NEW MOUTH-GAG, TOGETHER WITH THE CONSIDERATION OF OTHER POSSIBLE AND BETTER RESULTS FROM INTUBATION OF THE LARYNX.

The author presented a table of his twenty-five cases of intubation with seven recoveries. They were shown to be a severe class of cases. He had experimented to construct a better gag than those in use, and exhibited four of the new varieties made. One of these especially mentioned is so constructed as not to get out of place during the operation. A new feature of these gags is to have the teeth trough made somewhat swivel, so that they will fit any angle of the jaw—a child of any age.

The author thinks that he has discovered an indication for early operation. In two successful cases he was led to operate early, from noticing that the tension of the pulse was less during inspiration than during expiration, showing that there was suction of blood back into the pharynx during inspiration, because of the laryngeal constriction. This the author believes to be the first warning of danger and indication for intubation. In nine of his eighteen fatal cases death came at an average of twenty-six hours after intubation, and was attributable to the so-called aspiration pneumonia.

Dr. E. L. Shurley, of Detroit, Mich., presented a paper on

THE HOT-AIR TREATMENT OF PHTHISIS.

The paper was intended to simply report progress in the use of the Weigart apparatus. The author had used the apparatus in about twenty cases, but in only eight with that constancy and exclusiveness that would serve as a test.

Case I.—Obliged to discontinue treatment from pain caused to throat and lungs by the inhalations of hot air.

Case II.—Administered three or four times a day for fifteen minutes at 120° to 200° F., the latter only three times; 130° and 190° F. on several occasions. Immediate improvement followed.

Case III.—Caused nausea and vomiting, but hectic fever decreased and strength and flesh increased.

Case IV.—Febrile movement caused by treatment, also pain in the chest, with breathlessness and nausea; discontinued after ten days.

Case V.—Pulmonary and laryngeal phthisis. Administered for a week. Could not bear it longer.

Case VI.—Advanced stage of pulmonary phthisis. Given three times a day; could not bear it; discontinued.

Case VII.—Good effects.

Case VIII.—After fourteen days had to be stopped; apparently causing loss of appetite.

The author had found it impossible to apply the method for such a length of time as is reported to have been done in Germany.

Dr. Carl Seiler, of Philadelphia, read a paper entitled

CLINICAL OBSERVATIONS ON SOME CASES OF A PECULIAR CHARACTER,

in which he described the symptoms of a disease not yet well known, and which has as yet received no name. The

author had not seen the paper which he had recently learned that Dr. W. C. Glasgow read before the American Laryngological Association in Washington, at its late meeting, he therefore confined the paper to his own personal observations.

The run of symptoms of the cases observed by the author were summed up as follows:

1. Neuralgic muscular pains, usually in the back and chest, and often in the head, ears, and limbs.
2. Extreme debility.
3. Mucoid infiltration of the submucous tissues, and the formation of thin, white, pseudo-membranous patches on the surface of the mucous membrane.
4. Absence of febrile symptoms at first, and later, high temperature and low rate of pulse relatively.
5. Absence of albumen in the urine, and liability of heart failure.
6. Gradual melting away of the pseudo-membrane and the absence of any odor from it.
7. The wide geographical distribution in this country, and the infectious but not contagious nature of the disorder.
8. Finally, the specific action of benzoate of soda in relieving the symptoms promptly.

Dr. E. Cutter, of New York, reported the following two cases:

A case of

THYROTOMY FOR THE REMOVAL OF A SARCOMA,

operated on in 1886, was presented. The patient on whom the operation was performed could phonate. Reference was made to Dr. Hoffa's late paper, giving the statistics of thyrotomy since 1879, which were so successful as to justify the more frequent resort to this too-much dreaded operation. The case presented here was done without tracheotomy. The youngest case the reader had operated on was a child of twenty-two months—voice restored.

A case of

FIBROID OF THE RIGHT ARYTENOID,

operated on in 1868, by scarification, by a simple knife of the writer. Present state—permanent cure after twenty-one years.

A second like case of enlarged arytenoid, on an Irishman, was not successful. Tracheotomy tube inserted with relief. Patient visited Ohio. While there a physician removed the tube as useless, and the man died soon after.

Dr. Cutter proposed to change the name of the ventricular bands to "breath bands," on the ground that the false vocal cords are as true in their function as the true vocal cords, said function being the control of the breath in expiration, as seen in the laryngeal demonstrations by the author. The writer has waited five years for the systemic writers to rename these bands, with no response; hence this name is suggested.

(To be continued.)

## ASSOCIATION ITEMS.

Entertainments.—On Tuesday afternoon, June 25th, an excursion was made to the torpedo station. The visitors were received by Dr. J. C. Wise, of the Navy. A demonstration was made of the explosion of torpedoes, two being set off, and the guests were also instructed in some other of the mysteries of defensive warfare.

In the evening there was a reception in the Music Hall. The platform was tastefully decorated with flowers and potted plants, and some excellent music was furnished by the artillery band. An address of welcome was made by Mayor Coggeshall, on behalf of the citizens of Newport, and one by Dr. H. E. Turner, on behalf of the Newport physicians. Dr. Turner's address was devoted chiefly to sketches of the famous physicians of Newport, beginning with "the old French doctor," Norbert Félicien Vigneron, who came to the city and married one of its daughters in 1704. An oration on Dr. John Clarke, who procured the charter of Rhode Island from King Charles II., in 1663, was then delivered by ex-Senator W. P. Sheffield.

On Wednesday afternoon an excursion was made to Coasters' Island, to inspect the training-ship New Hampshire, and to witness a battalion drill of the boys of the Training School. The visitors were introduced by Dr. J. L. Neilson, of the Navy. In the evening there was a concert at the Opera House.

On Thursday afternoon the members of the Association, with their wives, visited Fort Adams and witnessed a light battery drill. They were introduced by Dr. S. M. Horton, of the Army. In the evening of the same day a reception was held in the parlors of the Ocean House. The music was furnished by the naval band.

On Friday afternoon the members went off for a clambake and a sail on Narraganset Bay, upon the invitation of the Rhode Island Medical Society.

Much credit is due the physicians of Newport for having made a success of the meeting in spite of many difficulties. The only complaint was of the lack of hotel accommodations, and this was, of course, unavoidable.

The Rush Monument Committee is having the experience of most other monument committees, and almost despairs of raising the needed $40,000. At the inception of the idea it was thought that this amount could be raised immediately by one-dollar subscriptions, but as yet the appeal has been responded to by only a fraction of the forty thousand.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, May* 16, 1889.

A. H. Smith, M.D., in the Chair.

Dr. W. Gilman Thompson read a paper (see p. 1) on

THE THERAPEUTIC VALUE OF OXYGEN INHALATION, WITH EXHIBITION OF ANIMALS UNDER HIGH PRESSURE OF OXYGEN.

Dr. J. West Roosevelt thought one explanation for convulsions occurring in animals sooner when under pressure of oxygen than under pressure of ordinary air was the fact that carbon dioxide was less soluble in compressed oxygen than in compressed air. He also thought that the amount of oxygen which the blood-plasma was capable of taking up was sufficiently variable to account for certain results in oxygen treatment of disease. The few cases of pneumonia in which benefit was supposed to have resulted from inhalation of compressed oxygen were not to be taken as conclusive, for in an equal number of cases other methods might have been, and frequently were, quite as successful.

In neurotic dyspnœa, referred to by the author, he thought benefit was to be derived from oxygen or any other forced form of inhalation. The treatment was useful from two stand-points: first, by calling the patient's attention to the process he breathed better, deeper; second, the moral impression led him to feel that he was suffering less from dyspnœa.

In simple anæmia of girls he had found patients do better under the use of oxygen in connection with the administration of iron than under iron alone. The explanation might not be ready, yet he could hardly avoid the conclusion that the diminished hæmoglobin was enabled, under oxygen pressure, to take up more oxygen, which amounted practically to breathing more pure air. It was not to be assumed that the blood-plasma was always saturated with oxygen. Like Dr. Thompson, he had seen markedly beneficial results in some cases belonging to the class of patients referred to, in whom the lung-surface exposed to the air was diminished.

Dr. George L. Peabody thought it was a matter of extreme difficulty to arrive at a conclusion as to the real value of a given therapeutic procedure when applied with others, especially in chronic diseases. Of course, reference was made to curative results, and not to immediate effects upon symptoms. The earlier attempts to impart more oxygen than usual to the body were made by placing materials which originated it into the alimentary canal, especially the chlorate of potassium. But materials which readily gave up their oxygen in the animal organism when introduced in any considerable quantity, must act as caustics at the site of application. Later it was surmised that the blood could take up unusual quantities of oxygen through the lungs. This might be possible if oxygen were simply absorbed, but such was not the case; it entered into chemical combination with the hæmoglobin of the blood. Under high pressure, ten atmospheres for example, the arterial blood did become somewhat richer in oxygen, but practically the amount of oxygen taken up depended upon the amount of hæmoglobin. In attempting to administer ozone in water it lost its character by chemical union with substances on the mucous surfaces, and might thus do actual harm, instead of proving to be a therapeutic measure. Dr. Peabody said he was among those who believed there was grave reason to doubt the therapeutic value of oxygen in the vast majority of cases in which it was used. He could not help believing that its efficacy in many symptomatic states was not greater than that of pure air administered in the same way. Oxygen inhalation seemed to be most justifiable in certain maladies attended by dyspnœa in which the blood was overcharged with carbonic acid. In diseases of the respiratory apparatus, with extreme dyspnœa and obstruction of the passages, as in severe catarrhal bronchitis, emphysema, asthma, pleuritic effusions, etc., relief might be obtained by oxygen inhalation.

His own experience with oxygen in illuminating-gas poisoning was the same as Dr. Thompson's. He had repeatedly used it in numerous instances for a long period without relieving the patient subjectively or objectively. He believed there was no justification for the use of oxygen in such affections as gout, uric acid diathesis, in which there was presumably imperfect oxidation. The benefit which had been claimed was probably due to pulmonary gymnastics, which the treatment necessitated. As to its value in anæmia and chlorosis, it must be remembered that patients with these affections frequently got well under most varying treatment.

Dr. Beverley Robinson thought he had seen absolute proof of the direct, immediate, therapeutic action of the inhalation of pure oxygen in the treatment of certain diseases. He had seen in numerous cases of simple anæmia much more marked improvement from the use of oxygen in combination with the use of iron than from other methods. He had also seen benefit from oxygen in albuminuria in atrophic nephritis. In a very large number of cases the oxygen treatment improved the digestion and assimilation, and in as far as it did that it seemed to Dr. Robinson to have a very wide field of utility. In phthisis he believed it had no direct curative effect, but he thought it proper to use it, because, first, it forced patients to expand their lungs; second, because there was reason to believe it might act in some degree as an antiseptic; third, it was useful in improving the nutrition. The amount of oxygen which the blood-plasma could appropriate was said to be limited, but the use of oxygen might stimulate the formation of hæmoglobin, and in that way be of benefit. He did not think the physician should allow himself to be guided in an absolute way in the oxygen treatment by the results of experimentation on animals.

Dr. Walter Mendelson was inclined, so far as concerned the clinical use of oxygen, to agree with Dr. Peabody. In cases of anæmia he had certainly seen some very marked results. For instance, in the case of an old man in the hospital various remedies were tried without effect until they began administering ten gallons of oxygen a day, when the improvement was marked. This might, however, have been due to the systematic exercise which the patient underwent during the inhalation, and the fact that he felt something active was being done. In dyspnœa from various causes he had generally seen immediate relief, although sometimes it was not very striking; but, as he recalled the cases, all the patients finally died, usually of the cause which had produced the dyspnœa. Still, he believed that in their last moments they were rendered more comfortable by the use of oxygen.

Dr. Putnam-Jacobi stated that in various forms of asphyxia it was observed that the amount of oxygen which the hæmoglobin carried was being continually diminished, although its physiological capacity might have a maximum limit. It was in these cases that Dr. Thompson had found evidence of benefit from oxygen inhalation, and it was in just such cases that one would expect the agent to have a therapeutic value. Here clinical experience coincided with physiological law. On the other hand, in the form of anæmia spoken of there was a reversed condition; the amount of hæmoglobin was diminished, and for that reason the system suffered want of oxygen. The way to increase the capacity of the blood for oxygen was to increase the metabolism in the tissues; this latter was stimulated by the presence of an increased amount of albumen.

The President confessed to a good deal of pleasure in finding that the paper and the discussion in the main confirmed the work which he had done in this direction twenty years ago. One point he thought deserved more emphasis, namely, that the blood in different conditions might not be fully saturated with oxygen, for the point of saturation corresponded to the full extreme physiological demand. If one's blood were fully saturated with oxygen under ordinary circumstances, how would it be when he took his place in the university boat-crew? He thought there was a margin, and a pretty wide one, between the conditions which ordinarily existed in life and the extreme provisions which nature had made for extraordinary conditions, and it was, perhaps, just within this margin that an additional supply of oxygen might be appropriated by the blood. For example, if there were a pathological condition present in which the demand for oxygen was not supplied with ordinary respiration, and might be supplied if the patient breathed thirty or forty times a minute with twice the usual exertion, the physician might tell the patient to breathe in that way, but he would know that ordinarily that would not be possible. To save the patient extreme respiratory effort to expand the lungs under ordinary conditions of the atmosphere, the object might be accomplished by giving him oxygen to inhale. It seemed to him that this very nearly marked the limit of benefit to be derived from oxygen treatment, except in those conditions pointed out by previous speakers, in which there was diminished surface exposure of oxygen within the lungs. The conditions in which most benefit had resulted in his experience had been, on the one hand, catarrhal troubles, as suffocating bronchitis, and opium-poisoning on the other. In opium-poisoning he had at one time supposed the benefit from oxygen inhalation was due to the fact that in the ordinary atmosphere the diminished number of respirations failed to supply the blood with sufficient oxygen, a difficulty which was overcome by supplying the agent in a pure state. But subsequently he had seen patients suffering from profound opium narcosis, with the respiration not diminished notably in frequency or amplitude, yet markedly benefited by oxygen inhalation. The inference was that for some reason the blood in opium-poisoning did not take up as much oxygen from ordinary air as from air containing oxygen in excess.

When it came to the question of inhaling oxygen under pressure, there were so many points to be considered of a mechanical nature that it was difficult to say how much the results were to be attributed to the influence of the

oxygen itself. He thought the convulsions, or even sudden deaths which were observed to take place after removal of the person or animal from compressed air, could be accounted for by the marked change in the distribution of the blood.

DR. THOMPSON, in closing the discussion, said some of the questions raised belonged to another department of the subject, which time did not permit him to fully consider. He would say, in reply to the President's remarks, that under ordinary respiration the arterial blood, as it left the lungs, had been found nearly saturated with oxygen. With regard to its taking up more oxygen under muscular exercise, here other questions, relating to rapidity of heart-action, etc., arose for consideration. In merely referring to the phase of the subject discussed by Dr. Putnam-Jacobi, he might say, as showing the importance of the unknown quantity, that animals suffering from asphyxia, after being deprived of a certain amount of oxygen, yet had more oxygen in their blood than some anæmic patients who did not appear to suffer from asphyxia in the least. Dr. Robinson having alluded to Brown-Séquard's assertion that pure oxygen was more irritating to the respiratory surfaces than nitrogen monoxide, Dr. Thompson said he had found, as had also other observers, no specially irritating effects, or burning of the tissues as it were, from pure oxygen.

THE PRESIDENT remarked that he had kept an animal four days in pure oxygen without any change in its condition.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 29, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 9 | 2 |
| Scarlet fever | 70 | 7 |
| Cerebro-spinal meningists | 3 | 3 |
| Measles | 86 | 6 |
| Diphtheria | 101 | 32 |
| Small-pox | 1 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

ASSOCIATION OF ACTING ASSISTANT SURGEONS.—The Association of the Acting Assistant Surgeons of the United States Army held its first annual meeting at Newport, R. I., on Monday evening, June 24th. Seventy-seven members have been enrolled. The following list of officers was elected for the ensuing year: *President*—A. Reeves Jackson, M.D.; *Vice-Presidents*—J. L. Ord, M.D.; A. J. Comfort, M.D.; D. S. Lamb, M.D. *Treasurer*—R. J. Dunglison, M.D. *Registrar*—Benjamin L. Holt, M.D. *Recorder*—W. Thornton Parker, M.D. *Council*—H. M. Deeble, S. S. Turner, W. E. Saben, H. R. Porter, J. P. Pratt, H. E. Turner, S. B. Stone, John S. Warren, S. O. L. Potter, E. W. Thompson, John T. Nagle. Applications for membership should be addressed to W. Thornton Parker, M.D., Narraganset Pier, R. I.

AMERICAN MEDICAL EDITORS' ASSOCIATION.—A meeting of this association was held at the Casino, in Newport, on Monday evening, June 24th, Dr. Wile, President, in the chair. In the absence of the Secretary, Dr. I. N. Love was elected Secretary *pro tem.* Dr. Wile read the address of the evening on "Our Duties as Journalists and the Reforms we should Persistently Advocate." The paper was discussed by Dr. Dulles, of Philadelphia, Dr. Conners, of Detroit, Dr. Davis, of Chicago, and Dr. Love, of St. Louis. The following officers were elected for the ensuing year: *President*—I. N. Love, of St. Louis; *Vice-President*—C. W. Dulles, of Philadelphia; *Secretary*—J. L. Gray, of Chicago.

THE LATE W. BARBOUR, M.D., ACTING ASSISTANT SURGEON, UNITED STATES ARMY.—At the Annual Meeting of the Association of Acting Assistant Surgeons, United States Army, held in the Casino, at Newport, R. I., June 24, 1889, the following resolutions were adopted:

*Resolved*, That the Association of Acting Assistant Surgeons, United States Army, has learned with sincere regret of the decease of the late W. Barbour, M.D., late Acting Assistant Surgeon, United States Army. The Medical Department of the Army has, by the death of Dr. Barbour, lost a faithful and valuable officer, the medical profession a worthy member, his many friends a sincere and manly companion. Dr. Barbour had been long in the service, and had made an honorable record. He died at the post of duty from disease contracted in efforts to save human life, and his faithfulness is a bright example of professional honor.

*Resolved*, That a copy of these resolutions be sent to the New York MEDICAL RECORD, and also to the Surgeon-General's Office for transmission to his family.

HENRY E. TURNER, M.D.,
RICHARD C. MOORE, M.D.,
W. THORNTON PARKER, M.D.,
*Committee.*

RESOLUTIONS ON THE DEATH OF DR. JAMES B. HUNTER.—At the recent meeting of the New York Obstetrical Society, the following preamble and resolutions were adopted:

*Whereas*, It has pleased Almighty God, in His infinite wisdom, to remove from our midst our friend and colleague, James Bradbridge Hunter, in the prime of his life and in the morning of his usefulness; therefore, be it

*Resolved*, That while we bow in submission before His supreme will, we recognize in His fiat the loss of one beloved and honored by us all for his gentle virtues and manly qualities; of one who will long be regretted, and whose place will forever remain unfilled among us.

*Resolved*, That in his removal the entire profession of medicine in America suffers a loss which cannot fail to be appreciated by all connected with it.

*Resolved*, That the kind sympathy of this Society, for which he has done so much, and its sincere condolence be tendered to his bereaved family; and that it cause a copy of these resolutions to be spread upon its minutes, published in several of the daily and medical journals of the city, and transmitted to his immediate relatives.

T. GAILLARD THOMAS, M.D.,
CLEMENT CLEVELAND, M.D.,
HENRY CLARKE COE, M.D., *Committee.*

At a meeting of the Faculty of the New York Polyclinic, held June 20, 1889, the following preamble and resolutions were adopted:

*Whereas*, This institution has been called upon to mourn the loss of its President, the late Dr. James B. Hunter; therefore, be it

*Resolved*, That in the death of Dr. Hunter the Faculty of the Polyclinic has lost an active, efficient, and conscientious leader, and the Institution a teacher of rare experience, untiring devotion, and distinguished success.

*Resolved*, That we recognize that in the abrupt termination of his laborious, able, and worthy career, the medical profession has lost one of its most accomplished and honored members, one whose death we profoundly deplore, and whose memory we venerate.

*Resolved*, That we extend to his family our heartiest sympathy, assuring them that we too have lost a trusted companion and a loyal friend.

*Resolved*, That a copy of these resolutions be presented to the family of Dr. Hunter, and that they be published in the *New York Medical Journal*, THE MEDICAL RECORD, and the *American Journal of Obstetrics.*

(Signed)] PAUL F. MUNDÉ,
E. B. BRONSON,
D. B. DELAVAN,

### YELLOW FEVER.[1]

BY WOLFRED NELSON, C.M., M.D.,

MEMBER OF THE COLLEGE OF PHYSICIANS AND SURGEONS, PROVINCE OF QUEBEC, CANADA; LATE STATE BOARD OF HEALTH, PANAMA, SOUTH AMERICA, ETC.

MR. PRESIDENT AND GENTLEMEN: With your kind permission I shall read a brief paper on yellow fever, a theme at once interesting to all students of medicine, and presumably of marked interest to my confrères in the "Sunny South."

In what follows, I shall refer to my own experience of this dread disease at Panama, on the Pacific, and Colon, on the Atlantic, both ports of the Isthmus of Panama; my studies and observations on the West coast of Mexico, where I studied and traced its epidemics of 1883 and 1884; my experience in the hospitals of Cuba; and finally my visit to Florida, in the fall of 1887, when I deliberately forecast the epidemic that swept Jacksonville in 1888. My letter of warning to the people of Florida was published in the *Times-Union*, of Jacksonville, November 30, 1887, and was recalled *when the disease was upon them.*

Now, to return to the Isthmus of Panama, where I lived and practised from 1880 to 1885. I was back there twice in 1886, and twice in 1888, thus, to use an expressive phrase, bringing my knowledge down to date.

The yellow fever of the Isthmus of Panama I describe thus: It is an acute infectious disease, a specific fever, ordinarily not contagious; but under certain atmospheric conditions, not yet fully explained, the disease undoubtedly develops contagious properties and epidemics result.

Yellow fever is ushered in in a variety of ways. It may be preceded by languor or malaise. The invasion may be abrupt. Generally characterized by a chill, often very severe, lasting one, two, or three hours; the duration of the chill having a marked significance, severe chills marking nearly all fatal cases. Again, the disease may be ushered in by sudden nausea and faintness, without any warning, as in my own case during the Isthmian epidemic of 1880. Headache is always met with. I know of no exception to this statement. Frontal headache, a flushed face, and gastric irritability in new-comers within the yellow fever zone, is always very suspicious, a fact specially referred to in Dr. Belot's admirable book, "La Fièvre Jaune à La Havane." Generally the headache is frontal; it may be bi-parietal and occasionally occipito-frontal, but, to repeat, marked headache always. In dealing with specific yellow fever of the Isthmus of Panama, which, if respectability depends on its antiquity, is the oldest, most respectable, and fatal variety known—a history of constipation obtains in nearly all cases. I can recall but a single case as an exception to this well-known rule, and it was a case in my practice where the disease had been preceded by a malarial diarrhœa. No condition of health gives immunity. It aims at all, be they healthy or unhealthy. It has a specific rôle. From early youth to advanced age it pursues its death-dealing mission. It is true that the mortality among children is less than at puberty and beyond. Pains in the legs and sacral region, the latter often intense and agonizing. I shall never forget my own experience. It seemed as if a legion of fiends were trying to dig out—if I may use the expression—my sacrum with red-hot pincers. The pain is excruciating and indescribable. In the majority of patients, the face was red, just like the face is in scarlet fever—the boiled lobster color. The eyes at first were clear, providing that there had been no antecedent hepatic disease; later they became suffused, injected. The skin was hot and dry. In many cases a peculiar biting heat was felt (like the *calor mordax* of pneumonia). It produced a strange sensation, resembling a current of electricity playing over the extended head. Pulse hard and slow, varying from sixty-five to eighty. Temperature, first stage, 100° to 103°; where the cases proved fatal, in the first stage, rising to 104°, 106°, and 107°, the latter being the highest temperature noted by me in my practice; to fall slightly just before death. In the second stage, or "period of calm," as it is termed, it feels a remission only. At the beginning of the third stage, or the stage of "secondary fever," it rises again. Respiration, as one would expect during the "hot stages," is hurried. At times a peculiar moaning respiration of indescribable sadness. It fills the room and the vicinity. The respirations varied from thirty to forty per minute, and at the close of the third stage fifty to sixty, becoming less with the fall of the temperature just before death. Great thirst, nothing appeases it. Restlessness, no position giving any ease. Urine, at invasion, normal but high-colored. In the majority of cases on the Isthmus of Panama the patients died during the first stage, such was the blood-destroying intensity of the disease when all, or nearly all, of the symptoms detailed and to be detailed, appeared. They do not appear in any stated order.

Within twenty-fours hours of invasion all the symptoms are intensified. Sacral pain and headache increasing; gastric disturbance and epigastric tenderness developing early in many cases, the slightest pressure over the stomach causing intense pain and eliciting sharp cries. In cases where the brain symptoms were very marked, in some where patients were unconscious, the slightest pressure produced a contortion of the face and body. If deep-seated pressure was made they writhed on their beds, but the instant that it was removed they became quiet again. Next, nausea and vomiting, at first a clear fluid, well named "white vomit" by Surgeon-General Blair, of British Guiana, South America. Tongue at first slightly coated. I am dealing with complicated cases. In patients who had suffered from intermittents, or bilious remittents, what is termed the characteristic tongue of yellow fever was not found. As stated it was slightly furred, later the fur increases from behind forward, the tips and edges take on a deep red. Gums also become a fiery red, also the mucous membrane of the mouth and throat. The whole mucous tract suffers. Later, in the majority of cases, sore throat is complained of, due to stripping of the mucous membrane. Blood oozes from the denuded tongue and gums, giving an indescribable fetor to the breath; at times it collects on the teeth. In some cases a peculiar and characteristic odor is exhaled from the patient's body. Once recognized, it never will be forgotten. It somewhat resembles *l'odeur du cadavre* of French authors. The late Dr. Stone, of Louisiana, was the first American writer, I believe, to recognize it. As he states, it is a very bad omen.

[1] Being a paper read before the State Medical Society of Arkansas Pine Bluff Meeting, May 28, 1889.

When patients die in the first stage, the urine always shows a large amount of albumen. The temperature remains high, 104° to 107° F. Delirium, often quiet, marks the latter temperature. In some cases extending over more time—beyond the fourth or fifth day—the albumen does not appear until the close of the second or the beginning of the third stage. Albumen is a *sine qua non.* I know of no yellow fever without it, nor do any of my many friends practising within the tropics. It never was absent in Isthmian cases. I never have seen or heard of a case of specific yellow fever without it; never, either in the practice of Dr. L. Girerd, late Surgeon-in-Chief Panama Canal Company, in that of Dr. Didier, of the same service, or in the cases seen by my brother, the late Dr. George W. Nelson, at one time my partner, and later Resident Surgeon at the Canal Hospitals, Huerta Galla, Panama, giving a combined experience of hundreds and hundreds of cases. During an epidemic at Colon, in the fall of 1883, it swept the shipping, over one hundred and fifty cases, nearly all fatal. Again albumen in all cases. Suppression of urine is a late, and generally among the last symptoms. Where it is marked, they seldom recover. The bowels, if freely acted upon by the sulphate of soda, to be referred to, may not furnish any early information, diarrhœal motions produced by the soda being followed by "black vomit motions" in many fatal cases. These motions may precede or follow black vomit. No rule is absolute, or such material, well named, may only be seen at the autopsy. Black vomit follows the constant retching and the "white vomit" of Blair. Black vomit is happily named, and shows innumerable fine particles or flocculi named black vomit or "coffee ground vomit," or the *marc de café* of the French writers, whose books on yellow fever are among the latest and very best. Frequently patients, without the slightest warning, commence violent vomiting. It pours forth from mouth and nostrils, often threatening to choke them. I have seen a patient resting quietly on his back after the subsidence of the gnawing sacral pain, when a perfect flood of black vomit has spurted from his mouth and nostrils up into the air, over bedding, mosquito curtains, and the nurse. An old and intelligent writer on yellow fever, Dr. Dowell, has been singularly happy in his remark, that it is *per saltum.* So it is.

Here, I must pause and divide my yellow fever cases into two classes, and shall state that such are met on the Isthmus of Panama. One class I took the liberty of naming "uncomplicated," the other "complicated." By uncomplicated, I mean the disease occurring in new-comers. In these, brain symptoms and delirium were common. Such, almost without the classic exception, died. I never knew one to recover. The possession of full health meant rich blood and a better culture-fluid for the germs that destroy it—the absolute destruction of the blood being but a matter of three or four days. I can best illustrate this by a case in the practice of my valued friend, Dr. L. Girerd, to-day a retired practitioner living in Paris. In the case referred to, on the fourth day of the disease, he failed to get a single red corpuscle in the blood—not one. The heart was driving a fluid through the vessels—one incapable of nourishing the brain tissues. A fluid wholly devoid of the life-sustaining oxygen carried the red corpuscles. His crucial microscopic work revealed a fluid, and in it the débris of corpuscles; or, to use the old time word that I have applied to this condition in yellow fever, a necremia, or death of the blood. His patient, a titled foreigner, a magnificent specimen of manhood, who stood six feet four inches in his stockings, died a few hours later. The "complicated" cases occurred in those who had been on the Isthmus from six months to sixteen years, and of course were profoundly malarious. I say of course, as no man, woman, or child there escapes intense paludal poisoning. Sixteen years had failed to give the so-called acclimation to an American, Captain Dean. Specific yellow fever cut him off; he was my patient. An elderly Italian, M. Georgetti, after thirty-seven years' residence at Panama, died of specific yellow fever. I personally know a French gentleman in Guaymas, Mexico, who has spent over forty years on both coasts of Mexico. He went through epidemic after epidemic unscathed, but in the thirty-sixth year of his residence, after passing through the Guaymas epidemic of 1883, he came down with the disease in 1884, when a few cases appeared, as is usual following *all epidemics within the tropics*, and just escaped dying. He in person related his experience to me. Acclimation is only so-called; it is a myth, but quite in keeping with a lot of our gross ignorance regarding yellow fever. Nothing, absolutely nothing, protects against specific yellow fever, except having had the disease, a fact well known to all close students of the disease within the tropics.

With this digression as a preparatory statement I shall next consider the second stage, or "period of calm," as it is termed. There is a marked fall of temperature, but merely a remission, and most deceptive and dangerous it is. I can best illustrate this by actual cases. In two cases, both mine, during the epidemic of 1880; new arrivals; just married; he a Frenchman and Consul for France; she a Portuguese, aged seventeen. They had passed the first stage. His temperature had ran up to 106° F., hers to 105° F. Then came the deceptive "period of calm;" they felt so well that, despite my emphatic orders, they got up and walked about. He was in one room and she in another. In the woman's case, the secondary fever came on that night, together with a copious "vaginal hemorrhage," practically the equivalent of black vomit. She died within twelve hours of her walking about her rooms. His temperature again ran up. He died the next day. She, poor girl, was laid out in her wedding finery. They occupy a single grave in the Foreign Cemetery at Panama. Such, gentlemen, is malignant yellow fever as I know it.

As I have stated, yellow fever may be a disease of a single "access" or paroxysm. When it is so, the patient dies or enters on convalescence, such being the milder cases in Panama. Thus, it resolves itself into a sharp, clearly defined fever of a single paroxysm, or "access," as the French so expressively term it. As nearly all attacked died, the milder cases were the exceptions. In the great majority the "period of calm" was deceptive, the slightest imprudence on the part of the patient ending in death later, the remission—I have seen the temperature as low as 99 °F.—lasting from twenty-four to thirty-six hours; in cases marked by long chills, but twenty-four hours to merge into the third stage of the disease, or that of "secondary fever." I have faced three epidemics of small-pox, one at home, in Montreal, and two at Panama. The severe chills in that disease, initiating the severe and confluent cases, the high primary fever, the second stage, to merge into the high temperature of the secondary fever, consequent blood changes, and death. These cases, so familiar to me, have caused much thinking in connection with my studies in yellow fever and its blood changes. In a fatal case of confluent small-pox at Panama, without the slightest warning, I have seen a fluid that to the eyes was identical with black vomit, spurt from the mouth, high in air, over everything, staining the bedding just like black vomit; it was *per saltum.* To our life-currents we must look for information.

In the "third stage" the albumen appears, that is, if absent at close of "period of calm," it is invariably met here. Black vomit and black vomit motions, suppression of urine, brain symptoms, etc., in cases ending fatally in this stage, all the symptoms crowd each other, and death closes the scene.

In "uncomplicated" cases, or where violent delirium may be met, many painful scenes result. A young Englishman, the picture of health, as attested by his magnificent physique and rosy cheeks, was stricken on landing. He was my patient. The case closed with furious delirium. Four men had to take turns in holding him, until death closed one of the saddest of sights.

A few remarks regarding the "fever of acclimation" of some writers. This, mark you, is generally preceded by a slight chill, a rapid pulse, a flushed face, suffused eyes, with a trace of albumen in the urine—in a word, it is a very, very mild form of yellow fever, the febrile movement lasting twenty-four to thirty-six hours, the mildest type of an "access." Failing a trace of albumen, it is not a fever of acclimation—that is, to a tropical physician—and without the other symptoms, no subsequent protection may be expected. In fact, some profound students of the disease within the tropics consider it but a temporary protection; that in seasons of epidemic, while such are exposed in a lesser degree, still they are liable to contract the severe type.

Such, briefly told, is yellow fever on the Isthmus of Panama. I have seen and attended it, in both cities, Colon and Panama. I wish to add that it and other tropical diseases have caused, at a low estimate, fully 20.000 deaths on the line of the Panama Canal. The New York *World* of May 18, 1889, credits the French Consul at Colon with saying that 15,000 Frenchmen have died. This probably is a mistake. I believe 20,000, all told, will be a generous estimate. The heaviest dying known to me was in 1884, during that epidemic at Colon, in the shipping and on the Isthmus. In an article in *Harper's Weekly* of July 4, 1885, I placed the death-rate for that month at 653 officers and men of the Canal Company. I obtained the figures from an inside source. The Canal Company's statements, as published in *Le Bulletin du Canal Interocéanique*, were as mendacious as they were misleading. De Lesseps' last ditch, that absurd creation of a man in his second childhood, has cost 20,000 lives, over $200,000,000 in gold, has ruined hundreds of thousands of petty investors in France. Up to the hour of the crash, De Lesseps in person, while knowing the full truth, unblushingly told his fictions. Since 1884 he has known the whole truth. He is a wicked old man, who should be buried alive under his fictions.

Many of our confrères have fallen in the Isthmus. Some noble fellows are buried there—yellow fever, dysentry, and pernicious fever. Yellow fever must be seen and studied in its own habitats. The Isthmus is one of the earliest.

My visit to Tampa in November, 1887, impressed me in many ways, but what greatly interested me was to hear of cases of *non-albuminuric yellow fever*. These cases of so-called yellow fever, I believe, furnish that class of people who have had yellow fever two and three times. As may be inferred, I have no faith in any yellow fever without the invariable presence of albumen in the urine. I have yet to meet with or read of a well-authenticated case of secondary yellow fever. Nor do I know a single physician who has seen one.

Now I come to the subject of treatment; and here I most emphatically state that yellow fever has no treatment properly so-called. The host of so-called treatments justify my statement. How can a disease, according to the old view, characterized by the symptoms described by me, have one? Four centuries seem to have taught the profession nothing, or next to it. All that has been known with absolute certainty is that people got yellow fever and died; the world heard of the dying, and that from Cuba it makes periodic invasions of the Sunny South. The treatment of yellow fever is purely symptomatic, my early treatment up to 1884, and was that of the "Old School." May God forgive it for its ignorance and charlatanism! Many authors have made a *réchauffé* or rehash of the experience of others, they never having seen a case themselves. They are responsible for much ignorance, *if not worse*. Having tried all the so-called orthodox treatments, I, previous to the fall of 1884, settled on the following: On being called to see a patient at the outset, I played a trump card and made quinine the diagnostic agent. We must bear in mind that a few hours in such cases may mean a life saved or lost. The following was the mixture:

℞. Quin. sulph ..... ℥ j.
Acid. sulph. dil., B. Phar..... ℥ ij.
Soda sulph..... ℥ j.
Tinct. Card. co..... ℥ ij.
Aq ..... ad ℥ viij.

Misce fiat mistura. Sig.: Take a quarter at once and repeat in two hours.

This mixture, given French fashion, in potions, or portions, well diluted with water, made a perfect solution and was readily absorbed. It was my "multicharge gun." It gave me the best results. Hot baths. Pilocarpine in one case, aconite, etc., were in order, to produce free action of the skin. If the cases were purely malarial, the quinine and sulphate of soda met all the indications. The sulphate of soda acts like a charm, free, bilious motions following. Every dose contained fifteen grains of quinine and half an ounce of sulphate of soda. If after two doses the temperature remained high, 100° and upward, with the usual symptoms, yellow fever was the verdict. Valuable time had been saved; the bowels freely acted upon, a most important indication. Later, I added to this treatment the following: A phosphoric acid mixture every hour or two, largely diluted with water; gave it and it only, purposely to bring about an acid condition of the blood. In a few words, to make it wholly uninhabitable to the germs. I adopted this course only after serious thought, and said to a medical friend, "My next patient with yellow fever gets well or dies on phosphoric acid." I explained it to two friends, Dr. L. Girerd and Dr. Arthur Gore, who saw my cases; also, to Dr. Bransford, United States Navy, who crossed the Isthmus on his way to Nicaragua. Previous to my adoption of this purely acid treatment, following the quinine and soda mixture, my patients kept on dying in a way that was simply appalling. Not that I lost more than my confrères. Our helplessness dazed me. As stated, after mature deliberation, I settled on phosphoric acid, well diluted, for life or death. Three cases so treated, all in succession, got well, an absolutely unheard of thing there. I had friends see them, knowing as I do what unbelief and professional jealously will do. My reasoning was sound. The acid did not destroy the oxygen-bearing function of the red corpuscles, while the germs of the yellow fever did, and so killed my patients. By rendering the blood acid these germs could not live and reproduce. They were destroyed *in situ* and the blood ceased to be a culture-fluid. Any student of medicine familiar with bacilli and their cultures, knows full well that even faintly acid solutions are fatal to the propagation of bacilli. Such was my reasoning as far back as 1884. I have the notes on those cases, taking full notes on all, as I had been taught to do while a student at the Montreal General Hospital, 1868-72.

The blood is the habitat of the germs of yellow fever. When my first case in the series of three demanded my attention, alas! I could not procure a reliable phosphoric acid, when I had to fall back on a formula published on p. 93, "United States Dispensatory," being that proposed by Mr. James T. Shinn, *American Journal of Pharmacy*, October, 1880, thus: "*Liquor Acidi Phosporici*. A similar preparation, under the name of Horsford's Acid Phosphate, has a large use in this country. The formula is as follows: *Liquor Acidi Phosphorici* (without iron); Calcii phosphat., 384 grains; Magnesii phosphat., 256 grains; Potassii phosphat., 192 grains; Acidi phosphorici (60 per cent.), 640 minims; Aq., q. s. to make a pint." As stated, not being able to procure a reliable phosphoric acid, I was forced to use Horsford's Acid phosphate. It, as I knew, was a standard preparation of uniform strength and excellence. I strongly object to employing a patent preparation, so to speak. Its contents or make-up was known, and it was "Hobson's choice." The preparation did all that I anticipated, and I give its formula as found in the "United States Dispensatory." I knew what I used. It is essentially a strong acid mixture.

To repeat, having given my quinine and sulphate of soda mixture, thus securing free motions from the bowels, the malarial element being eliminated by the non-effect

of the quinine; I then treated for yellow fever, thus: To bring about free action of the hot and burning skin was absolutely necessary. As stated at first, I tried hot baths, aconite, etc., and abandoned them, using a simpler and more effective means, in a vapor-bath, named in Peru as "Dr. Wilson's treatment," being that of an English physician who used it with great success during an epidemic there in 1854, and later. The patient was placed on a chair—one with a wooden seat—all clothing being removed; he was covered with blankets tucked in closely under the chin. A spirit-lamp was lit and placed under the chair, thus furnishing heat and vapor. To Dr. Wilson's vapor-bath I added a foot-bath, all under the blankets, the water as hot as the patient could bear it. Finally I grafted on some Jamaican treatment, giving a pint of hot lemonade or orange-leaf tea. Under this triad, a profuse perspiration followed, usually within ten minutes; it fairly ran off them. As soon as it was freely established they felt better. The scarlet hue of the face faded. The hard pulse became softer. If the bath caused faintness, that was guarded against by a shorter exposure. With this I had no unpleasant symptoms, but with nitrate of pilocarpine, profound pallor and faintness in a well-nourished man caused me alarm. I tried it in but a single case, and that was previous to my knowing of Wilson's vapor-bath. The necessary exposure being made, ten to fifteen or twenty minutes, the patient stood up, the chair was slipped from below the blankets and he was lifted into bed *en masse* to prevent any escape of heat or moisture. More blankets were put over him. In some cases the perspiring lasted one or two hours, to the marked relief of the patient and the lessening of all the symptoms. After a variable time, the skin again became hot and dry, when the same procedure was repeated, as often as necessary. Thus, two highly important indications were met at the very outset. First, under the quinine and soda, free motions from the bowels were secured; remember the marked constipation in these cases, often extending over three or four days, while the man had been eating as usual. Secondly, full and free action of the skin. According to my way of thinking and reasoning, the patient was placed under the most favorable conditions for fighting the disease. Generally large quantities of fecal matter were voided, and the pores were thoroughly opened. Next, the rest of the treatment was in order. It was of the simplest. A teaspoonful of the acid phosphate in a half tumbler of water, every hour or two, day and night, for the first twenty-four hours. It never caused nausea. I continued it for two or three days, according to temperature of patient and symptoms. The bowels continued to act freely—bilious motions. Later they became very dark under the acid. Previously, I had used sinapisms and a lot of things recommended by the books, and those supposed to be experienced in treating the disease. The sinapisms were placed over the stomach to try and check the distressing vomiting. At times they were beneficial; again, useless. Diet in these cases is a matter of very small importance. They were too busy with the disease. I fail to recall a single case where food of any kind was asked for. The highly irritable stomach must be remembered. Iced milk and beef broth in very small quantities, at frequent intervals, *if the stomach tolerates them.* Iced lemonade and pure soda water. Small pieces of ice allowed to dissolve in the mouth. I gave champagne a fair trial, and abandoned it. I am satisfied that the purely acid treatment is ample. The simpler the treatment the better. The quinine and sulphate of soda mixture, vapor-baths *à la* Wilson, and the acid meet all requirements. I abandoned the old time treatment. As I have already informed you, I had three recoveries, one after the other, all in infected premises where the previously attacked had died. These recoveries were in the fall of 1884. Early in the spring of 1885—March—I left for my annual holiday, visiting Nicaragua, when I returned to the Isthmus, to leave it, April 25th, for New York City.

Three swallows do not make a summer, nor do I claim that three successive recoveries are everything; but as nearly all attacked died, I do earnestly claim that three successive cases getting well furnish food for thought. Personally, I am satisfied that, by persistently acidulating the life-currents, they ceased to be blood-heat culture-fluids for the germs of yellow fever. I say germs. The following facts, I believe, will strengthen my claim that three successive recoveries were absolutely unheard of at Panama. A few words regarding the dying from yellow fever thereaway. I can recall twenty-seven admissions to the yellow fever ward of the Canal Hospitals, Panama, with but a single recovery. My brother, the late Dr. George W. Nelson, then Resident Surgeon, furnished me with the figures. Of forty-two cases sent to the Charity Hospital, Panama, during the epidemic of 1880, when I had the disease, not a single recovery. As a concluding statement, I could amplify them to any extent—the Dingler expedition. Mr. Dingler and Mrs. Dingler, accompanied by Mr. and Miss Dingler, and a party of canal engineers—all told, a party of thirty-three—arrived at Colon in October, 1883; Mr. Dingler being the new Director-General of the canal works. Within six weeks of landing Count de Cuerno and Mr. Zimmerman were dead—specific yellow fever. Within fifteen months of the landing of that party of thirty-three, fourteen had had yellow fever, and but one recovered; Mr. Dingler losing his wife, son, and daughter. He was very patient and had been on the Isthmus previously. His regular life, no doubt, was the factor that saved him. Contrast three successive recoveries with the above—my cases were specific yellow fever.

As previously intimated, yellow fever spares none. While it is quite true that total abstainers have been swept away by it, it is equally true that, even in the severest cases, they have recovered, where the moderate drinker was lost from the start. Time and again, my own experience has confirmed this. The regular life, particularly within the tropics, is its own reward. In "Ziemssen's Encyclopædia," vol. ii., in the article on yellow fever much valuable information will be found on this very subject—the value of total abstinence. "Panama in 1855," Harper Bros., New York. "The Handbook of the Panama Railway," 1860, Dr. Otis, Harper Bros. Dr. L. Girerd's work on "Panama," published in 1883, in French, in Paris. All contain much information regarding that land of pestilence and death, as well as "Five Years in Panama," 1889, Belford, Clarke & Co., New York.

In reference to the inestimable benefits of total abstinence within the tropics, it simply confirms the opinion of a valued friend at Panama, the Consul-General of the United States, who, when asked, "How do you live in the tropics?" wittily replied: "It all depends on the *liver.*" So it does. An alcoholic liver in yellow fever means death.

The time allowed for the reading of this paper necessitates my leaving out much that I should like to discuss. I must ignore the interesting history of the disease and hasten on.

A few words or points on the after-treatment. The treatment during convalescence calls for constant watchfulness. It is here that malarial symptoms crop up in the cases of those who have been at Panama a few months. Dr. L. Girerd examined the blood of hundreds on arrival, and found it normal, in no case showing the malarial bacillus. After the first month he re-examined scores of them; the blood of all these showed it, simply confirming the statements to be found in Dr. Tomes' work, "Panama in 1855," statements amplified in Dr. L. Girerd's work.

To return to the stage of convalescence. I have known a beefsteak to cause death on the tenth day. During convalescence such patients are simply ravenous. Well do I recall my own intense hunger. Slops are in order, fluid food, given at short intervals, not to overload the stomach. Its irritability lasts for weeks and weeks. Bathing, a thorough washing of the patient's body and hair daily, in a weak carbolic bath, the thorough disinfection of the patient's effects and room.

The majority of cases were fatal on or before the fifth day, closing with black vomit, suppression of the urine, etc. In such patients it was a fever of single "access," or paroxysm. Other cases passed through the "period of calm" and died in the third stage, or that of "secondary fever," from the sixth to the ninth day. Cases of a typhoid character were rare. I saw but one, being that of my friend Dr. Arthur Gore, now in San Francisco, Cal.

The sequelæ: Boils, pimples, parotid swellings, and intermittent fever. Jaundice—It was of a rich canary color. It lasted a whole month. People were never curious about it, or anxious to ask me questions—not any.

Now for a very brief reference to *post-mortem* appearances. My small experience under this heading simply confirms what an old and clear-headed American writer has stated: "Yellow fever has no pathology." I refer to Dr. Grenville Dowell, whose little *brochure* contains a mine of information, or what the great French undertaker, M. de Lesseps, calls "an arsenal of facts."

The *post-mortem* findings are so variable in patients cut off by the same symptoms that no reliance can be placed upon them. I deem it a blood disease, pure and simple, and if my view is accepted, absence of any marked pathological changes, save in the blood itself, must be expected.

The liver: It presented a variety of conditions. I have found it fatty; again, fatty on section, showing an immense quantity of oil-globules; again, perfectly normal in size and color. The chamois-colored liver is supposed to be the characteristic liver. I never saw but one, and it was the only one found in nearly one hundred autopsies made at the Canal Hospitals, Panama, by Dr. S. Didier, a gentleman profoundly versed in yellow fever. He was born in one of its habitats, the Island of Martinique, French West Indies.

The kidneys: Nothing constant. I met them large and small; again, perfectly normal to the eye.

The stomach: This organ presented signs of acute inflammation. Generally its coats were thickened; it contained more or less black vomit; I saw nearly a pint in one case; its inner surface showing innumerable pink points or *foci* of congestion, and small deposits of blood. Dr. Castellanos, a physician to the Charity Hospital, Panama, a Spaniard, and formerly a hospital surgeon in Cuba, told me that it was the only constant condition found by him, and he, while there in Cuba, had made nearly one hundred and fifty autopsies.

The brain I never examined. Dr. L. Didier found nothing worthy of remark in his large experience. Nothing.

The blood: I always found it in a perfectly fluid condition. Remember the destruction of the corpuscles and the great amount of albumen eliminated by the kidneys. Its specific gravity, taken by me two hours after death, was nearly normal. To this fluid we must direct our whole attention. To repeat, I deem it a blood disease, pure and simple, and have held this view since 1884. Death in these cases is due to a true necræmia. If this view, which I believe is peculiar to myself, be proven, we have an explanation of the majority of symptoms of yellow fever, and, as already stated, it explains the absence of any characteristic pathological changes, save in the blood itself.

The brain symptoms are due purely and simply to the destruction of our oxygen carriers, the red corpuscles. The great Virchow attributes loss of consciousness to their failure to carry oxygen. By rendering the blood uninhabitable to the germs that prey upon and destroy the corpuscles, we triumph. Much remains to be explained about yellow fever. Many honest and patient toilers are at work on this great problem. I believe that with the discovery of the specific germ by Dr. Domingo Freire, of Rio de Janeiro, Brazil; by Dr. L. Girerd, at Panama, and its discovery by Dr. Carlos Findlay, in Havana; to his and the work of his friend, Dr. Delgado, of that city; add to this our knowledge of the truly wonderful strides made by these gentlemen in their bacteriological studies and inoculations; to the above, by acidulating the blood, as I have done, where it has invaded the system; with such factors the future seems full of hope to me. May it prove so. Having digressed I must get back to the *post-mortem* findings.

The bladder: Generally a few drachms of highly albuminous urine were found. Remember the suppression.

Black vomit has a peculiar odor, and is slightly acid to the taste. To clear up a vexed point in my mind, I collected some in one of my cases and tasted of it. It required a little courage, but I was in earnest and working for results. I may state, *inter alia*, that it will never compete favorably with other beverages. The "vomit," on settling, deposits coffee-ground "particles," the fluid above being the color of weak black tea. Black vomit is not bilious vomit. I tasted it to clear up this very point. Black vomit, as a symptom, is of grave import. It indicates advanced blood-changes, the beginning of the necræmia. While at Panama I sent friends specimens of my late patients. My rooms were miniature graveyards. Some "black vomit" sent to my old classmate, Dr. William Osler, then Professor of Clinical Medicine in the University of Pennsylvania, with other material, furnished *pabulum* for a lecture on "Vomited Matters." To-day he is Professor of Practice of Medicine in the Johns Hopkins University, Baltimore, Md., and Physician-in-Chief to the magnificent hospital of the same name.

To recapitulate: Now that Drs. Freire, Girerd, Findlay, and Delgado have found the same germ, Dr. Domingo Freire being the first investigator and its discoverer, to him the honor and credit are due. He caused others to work. Now that this has been accomplished, I firmly believe a new era is at hand, and that soon this constant reproach to our profession and much-vaunted modern civilization, the sway of yellow fever, is about to receive its *coup de grâce*. Inoculations will protect man against this awful disease as vaccine does against smallpox. Dr. L. Girerd proved his good faith in such a vaccine, if the term is permissible, by making attenuated cultures of the microbes of specific yellow fever, and by inoculating himself; and without carrying it to the full protective influence, he allowed himself to be bitten by mosquitoes (Dr. Carlos Findlay's discovery) that had been feeding on a man in the yellow-fever ward of the Canal Hospital, a case of specific yellow fever; the fifth day the mosquitoes were disturbed and allowed to bite him. The result was a mild yellow fever. I translated his report, and it was published in the *Canada Medical Record*, Montreal, in the fall of 1886, together with an editorial.

With inoculations to protect and prevent, and the purely acid treatment where the germs have invaded the system; with these and a strictly scientific quarantine *à la* Dr. Joseph Holt, our profession can save the lives of hundreds of thousands in the future, who, but for such measures, would die like rotten sheep. The acid, I believe, is a germicide in these cases. I like the term and make no apology for using it. Intermittent fever, as we well know, thanks to the crucial work of Leveran, Girerd, and Osler, has its *bacillus malariæ;* quinine is its germicide.

When these things are thoroughly understood and put in practice, travel within the tropics will be divested of its terrors. People ere visiting them for business or pleasure will be inoculated, and with quarantines *à la* Dr. Joseph Holt, the commerce of nations will be almost free and untrammelled.

Here, gentlemen, I must say farewell. I have to thank you for your kind attention and patience. In the near future I trust that you will recall these statements made in the presence of the members of the State Medical Society of Arkansas, on this the 28th of May, 1889.

## THE INHIBITORY ACTION OF ANTISEPTICS.[1]

By G. W. McCASKEY, A.M., M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE, AND CLINICAL DISEASES OF THE CHEST AND NERVOUS SYSTEM, IN THE FORT WAYNE COLLEGE OF MEDICINE, FORT WAYNE, IND.

THE views of the advanced workers and thinkers in the field of bacteriology, in its relation to practical surgery, are fairly well crystallized and harmonious so far as the basal facts are concerned. It has appeared to me for some time, however, that there was an unaccountable failure to recognize the great practical importance of a well-known fact, viz., the power of weak antiseptic solutions to temporarily suspend the vital processes of micro-organisms. Carbolic acid, for instance, in solution of one to twenty, will kill the majority of germs in a few minutes' time; on the other hand, the same species which would be destroyed by the above-named solution, if placed in a solution of one to three hundred, would have all their functions suspended, but would retain their vitality for an indefinite period. In a solution of one to three hundred and fifty, however, they would flourish luxuriantly.[2] In other words, their physiological processes are suspended by contact with a solution one-fifteenth as strong as that required to destroy them. A solution materially weaker than this fails to exert any restraining influence.

The disposition to ignore this important biological law has been manifested in a variety of ways, but perhaps most prominently by the unwarranted assumption that antiseptics are useless, or worse than useless, in the treatment of wounds unless applied in solutions strong enough to kill the germs. I was particularly impressed with the fallacy of this position by an editorial which appeared in a leading metropolitan weekly a few months since. (See "A Reaction against Antiseptics," in THE MEDICAL RECORD for November 17, 1888.) In this editorial Dr. Saenger is quoted as follows: "The disinfection of a living tissue he considers to be impossible. Either the tissue is free from germs, in which case there is no need of an antimycotic, or it is infiltrated with pathogenic fungi, in which case it is impossible to destroy the fungi without at the same time seriously injuring the tissue." These views of Dr. Saenger, approvingly quoted by THE MEDICAL RECORD, I believe to fairly represent the deliberate judgment and "working formulæ" of a large and intelligent contingent of the medical profession. The position taken is very plausible, and, indeed, so far as the specific statements are concerned, is entirely unassailable. To use antiseptics in the absence of micro-organisms would, of course, be extremely irrational; while the direct application of antimycotics strong enough to immediately kill the germs would undoubtedly produce considerable injury to the tissues. But this is only a part of the truth, and it does not follow because of these facts that antiseptics are useless as applications to wound surfaces. Such a conclusion ignores the inhibitory law above referred to. To kill a pathogenic organism is one thing; to inhibit or suspend its growth and functional activity is quite another.

What does the inhibition of bacterial action mean from a clinical stand-point? This question is best answered by stating what it means physiologically, which is, suspension of all those secretory or excretory processes which result in the production of ptomaïnes; and also complete arrest of the multiplication or numerical growth of the micro-organisms. This fact is of the highest importance. Robbed of their power to produce the chemical poisons known as ptomaïnes, to which the morbid processes of septic wounds are due, and especially when, in addition to this, they are rendered powerless to increase in numbers, the few septic organisms which primarily gain access to a wound are as harmless as so many particles of lifeless organic or inorganic matter. So long as they do not functionate they can do no harm.

While the micro-organisms are thus rendered temporarily inert, another important fact is to be borne in mind. The longer the living tissue-cell remains in contact with micro-organisms in an inactive state, the lower becomes their vitality, and the greater becomes the probability that the internecine contest between the tissue-cell and the organism, to which Virchow long ago called attention, will result in a victory for the former. It might be answered that whatever inhibits the micro-organism will also lower the vitality of the tissue-cell. But this does not logically follow, because, among other reasons, the change in the life-state of the micro-organism is somatic, while in the case of the tissue-cell it is molecular, viewing the tissues as a mass. There are dynamic forces back of the tissue-cell, in the great mechanism of life of which it forms a part, which reinforce and sustain it. The micro-organism has no such forces in reserve.

It seems clear to me that the sweeping assertion that an antiseptic application to a septic wound is useless unless strong enough to exert a distinctly germicidal effect, is not only a scientific mistake but a dangerous fallacy, leading to erroneous practice. If everything constituting the paraphernalia and environment of an operation, down to the skin through which the incision is to be made, is absolutely aseptic the use of antiseptics would be absurd, for they must be regarded as irritants, and, as compared with sepsis, simply as the lesser of two evils. As has been repeatedly said, the object, and the only object, of antiseptics, is asepsis. To drench the virgin tissues with chemical irritants during the progress of an aseptic operation is not only unnecessary but positively injurious, and entirely contrary to the teachings of antiseptic surgery in the light of its latest achievements. But when a wound is known to be, or there is good reason for believing that it is, infected, and especially if the infection is recent, the case is quite different. The use of antiseptics, as strong as the tissues will tolerate without undue irritation, is certainly dictated by the information which we now possess. Who has not seen a post-partum septic fever disappear after, and undoubtedly in consequence of, the intra-uterine, or even intra-vaginal, injection of a one-half per cent. solution of carbolic acid solution or its equivalent? Who has not seen an offensive septic wound-discharge, perhaps with constitutional symptoms, disappear under a similar treatment? Yet we all know that such a solution is not germicidal, but only inhibitive. It is not strong enough to kill, and can only suspend physiological activities.

The conditions which determine the success or failure of weak antiseptic solutions in morbid conditions, such as those just mentioned, are not always clear. It is probably dependent in large measure upon the degree and depth of tissue infiltration which exists at the time such treatment is instituted. If, as often happens, the chemical products are largely formed upon the surface, the combined irrigant and inhibitive action removes the cause, and with it the symptoms, as if by magic. But if, on the other hand, the germs have permeated and made their habitat deeply in the tissues, they are manifestly beyond the reach of surface

[1] Read before the Fort Wayne Academy of Medicine, May 13, 1889.
[2] Cheyne's Antiseptic Surgery, p. 262.

applications. Infiltration of the tissues forming the boundaries of a wound can scarcely occur without considerable surface infection, where the greater part of the ptomaïnes would be manufactured, to be absorbed from thence into the blood and lymph spaces. Hence, even after tissue infiltration has taken place, surface irrigation with antiseptics in inhibitive doses would remove the poisons already formed on the surface, as well as a very important source of their continued formation.

There is an interesting medical aspect of this question to which I will briefly refer. It is this: Can the general infectious diseases be rationally treated, in the light of existing facts, by an attempt to convert the blood into a solution of antiseptics strong enough to restrain or entirely prevent the physiological activities of micro-organisms contained in it, by means of the inhibitive action above referred to? It must be conceded at once that the killing of these germs, while in the blood, by a direct germicidal action, is not within the range of possibility, unless entirely new facts are discovered. Their lethal dose is probably the same here as elsewhere. There is not a single fact, so far as I know, which would justify us in assuming a difference in this respect.

The possibility or impossibility of their inhibition in the blood ought to be capable of a decision coming within the range of highest probability, if not of certainty. Let us glance for a moment at the principal factors which must enter into the solution of the problem.

The blood vascular system of an average adult contains, we will assume, twelve pounds avoirdupois. It probably varies within pretty wide limits, according to state of health, character and quantity of diet, condition of the various secretions, etc. But this is sufficiently accurate to form the basis of a calculation.

As to the kind of antiseptic to be considered, it may be remarked in passing that the mercurial salts, while conceded to be the most potent germicides under proper chemical conditions, are not entitled to the slightest consideration in this connection, inasmuch as they are now known to combine with any albuminous fluid, such as the liquor sanguinis, forming an albuminate of mercury, which is absolutely inert as an antiseptic. In view of this fact, the administration of fractional, frequently repeated doses of mercuric chloride for an antiseptic effect upon the blood is absurd.

Let us take carbolic acid as the basis of our calculation. We now know that it takes a solution, at least as strong as one to three hundred, or one-third of one per cent., to exert an inhibitive influence upon the common forms of micro-organisms in laboratory experiments. About the same proportion in the blood, it is fair to assume, would be required to be effective.

Twelve pounds of blood represent eighty-four thousand grains. To make a one-third of one per cent. solution of this quantity of fluid would require two hundred and eighty grains of carbolic acid, or about half an ounce of the pure crystallized acid. A dose of eight grains is considered by Huseman to be dangerous. The difference between eight and two hundred and eighty is so enormous as to make any comments unnecessary. It is certainly obvious that no antiseptic can be introduced into the blood in sufficient quantity to make the latter represent an antiseptic solution strong enough to have the slightest restraining influence upon the development of micro-organisms. Eight grains, if evenly distributed through the mass of blood, would be less than one-thirtieth of the amount required. A child weighing twenty-five pounds, and having about two pounds of blood, would require forty-six grains of carbolic acid to make the necessary antiseptic solution of the blood. There is not the slightest reason for believing that the largest quantity which it is possible to introduce into the blood would have any effect whatever upon the life phenomena of any bacteria which it might contain.

To all these deductions from laboratory experiments it may be objected that they are belied by clinical experience at the bedside. But, so far as I know, the diseases in which the administration of antiseptics has appeared to have a germicidal, or, at least, a modifying effect upon the germs which are the efficient causes of all infectious disease, have been those in which (as in dysentery, typhoid fever, etc.) the micro-organisms find their principal habitat and base of operations in the alimentary canal. The germs are thus probably brought into actual contact with the antiseptic solutions before absorption, when they might easily be sufficiently concentrated to have at least an inhibitive influence, and, under certain circumstances, possibly an actual germicidal effect. And especially in reference to the mercurial salts, which are so largely used in this way, they could exert their specific effect without being rendered inert by a chemical combination with albumen. But whatever the explanation may be, it seems clear that we must look in some other direction for it than that of blood disinfection from antiseptics held by it in solution. The following conclusions are offered:

1. Solutions of antiseptics one-fifteenth as strong as those required to kill a given germ (its lethal dose) will render it functionally inactive, and consequently harmless, in wounds during the continued action of the antiseptic and for a variable time thereafter. This should be called its inhibitive dose.

2. In solutions materially weaker than one-fifteenth the lethal dose bacteria will flourish, to all appearance, quite as well as though no antiseptic were present.

3. The inhibitive doses of the various antiseptics should be as accurately determined and as widely known as are their lethal doses; and should be studied with special reference to the different species of pathogenic and putrefactive organisms.

4. If wounds were irrigated, either continuously or at brief intervals, with inhibitive doses of antiseptics, surface bacteria could not manufacture ptomaïnes, the chief or only cause of morbid wound processes. Fresh infection of the wound would also be impossible.

5. A sufficient quantity of antiseptics to render the blood inhibitive in its effect upon any organisms which it might contain cannot at present be introduced into it.

6. The beneficial effects following the administration of antiseptics in dysentery, typhoid fever, and other diseases of that type, are probably due to the direct action upon the germs of the antiseptics before their absorption.

---

## NOTES ON ENTERO-COLITIS IN INFANTS: ITS CAUSES AND TREATMENT.[1]

By JOHN LORD BABCOCK, M.D.,

ASSISTANT TO THE CHAIR OF CHILDREN'S DISEASES, ST. LOUIS POLYCLINIC.

When the genial sun of springtime opens the buds and greens the lawns, there always appear two concurrent phenomena in the medical journals. One of these is the article by the doctor who knows a great deal about cholera infantum, and the other is the advertisement of the patented baby-food man who knows a great deal more about it. Recognizing this fact, and in obedience to the unalterable law of this recurrence, I beg to offer the following notes, not as embodying a single idea that is new, but merely for the purpose of placing before you the general results of the study of a large amount of clinical material bearing upon an important subject.

The green and fetid diaper, like "the poor," we have with us always, and it is to this humble garment—which a friend of mine asserts to be the modest rudiment from which have been developed all of the beauties of the modern bustle—that we must direct our attention.

Before proceeding with the discussion of my subject, however, permit me a few words upon the closely allied, but very hackneyed, question of infant feeding by artificial means. In the clinic of the Post-graduate School of this city all of the proprietary foods have been weighed in the

[1] Read by title before the St. Louis Medical Society, May 18, 1889.

balance of practical experience and have been found wanting, although some of them have been found useful in emergencies, and those of them that involve the use of cow's milk are, to that extent, good. Many of them, as is well known, contain starchy substances, alleged to have been "converted into the soluble form of dextrine" by superheating. These foods, of course, do nourish children, and in many cases do it well; but their success is by no means universal, as we might be led to suppose by the advertising matter so copiously furnished us. Those consisting of "dried milk solids and soluble starch" are apt, in certain cases, to cause obstinate constipation, which in time produces intestinal irritation, so that the mother may be surprised to find her child, for this reason, suffering from a sudden and severe diarrhœa. They are by no means "ideal foods," and then our patients, who are numbered largely among the less wealthy classes, are not able to pay, and we ought not to ask them to pay, the advertising bills of these food-makers, which, I am told, form thirty per cent. of the cost of manufacturing (?) the article; for these foods when used exclusively are expensive. They have, however, a slight therapeutic value in checking a simple diarrhœa after the bowels are freed from irritation. The predigestion of milk with the animal ferments has been found in our cases to be impracticable. As has been well said, "the woman who can treat milk with the animal ferments does not have children."

The disgusting flavor of an over-digested sample of milk would make a well man ill, and one may imagine the results in the case of a sick child. This seems to be an instance of the cases in which the principle is sound, but the results unattainable in practice. Of course, in discussing this question, we must remember the inevitable baby that "ate anything," and was the healthiest baby in the recollection of the oldest inhabitant. Such an infant is almost always brought into the discussion of baby-feeding; but the survival of these remarkable youngsters on a diet of pie and pickles proves nothing, of course, but the well-known fact that a few children thrive on food upon which most children could not subsist. After a prolonged and careful study of this question from the stand-point of practice, we have come to the conclusion that the milk-and-cream food advocated by Dr. Arthur Meigs, of Philadelphia; Dr. Joseph Winters, of New York, and others, is, beyond any comparison, the best artificial food for infants. Its composition for an infant of six months is as follows: Milk, 3 parts; cream, 1 part; lime-water, 1 part; boiled water, 2 parts; and sugar of milk, 1 part. Solution of bicarbonate of soda, three grains to the ounce, may be substituted for the lime-water in case the baby is constipated. This food meets the general indication of resemblance to mother's milk in specific gravity, richness in fats, alkalinity, and sweetness.

The "hardness of the curd of cow's milk" is largely a bugbear that is kept before the profession by the public-spirited advertisers of prepared foods, who make such heroic efforts to defend our little patients from the poisonous curd of the milk of the malevolent cow. A stomach that has any physiological activities left can digest, with certainty, small amounts of this food. When you have to do with a depraved organ, modify the food by increasing the proportion of cream and lime-water, and give it in small, often-repeated doses. You are then not at the mercy of compounds of an unknown nature, that have been on druggists' shelves for an unknown time, and contain an unknown variety and number of micro-organisms or products of decomposition. You have the matter of feeding in your own hands, and experience with this milk-and-cream food will soon teach you to modify it to suit individual cases.

Anyone can now sterilize and preserve milk by the familiar and simple process of steaming. It is only necessary to have a deep kettle with a perforated tin false bottom, a tight-fitting cover, and a flat-iron to place on this cover. Milk in cotton-plugged bottles, each containing enough for one feeding only, can be steamed in such a simple apparatus for twenty-five minutes, and will remain sweet and good until used. As is the case with all foods, this milk-and-cream preparation occasionally does not agree with a child, but in our experience it has failed less often than any other. In four such cases condensed milk, which is often a very good temporary food—though I think a bad one for prolonged use—did well. Three others took very kindly to malted milk, and two others seemed to have a selective affinity to the dried milk and dextrine food. Inasmuch as milk-sugar is rather expensive, one-fourth the amount of cane-sugar may be substituted in cases of healthy children over six months of age. But with all children younger than that, and with older ones who are suffering from bowel or stomach disturbances, the milk-sugar will be found decidedly preferable.

A word right here in regard to your milk supply. Milk is the doctor's sheet-anchor to windward in treating these cases; but you will find that among the poorer classes the habit prevails of running into "the store for a nickel's worth o' milk," and the milk they get is a common cause of intestinal disturbance among young children. I am informed by the manager of one of the large milk companies of the city, that they sell to these groceries their "separated" milk, that is, milk that has been skimmed three times, so that the uttermost morsel of cream has been removed. This skimmed milk is watered by its purchaser, and then brought up to a better color by the addition of a little good milk. Then, after standing for an indefinite time in close quarters with ham, bad butter, decaying potatoes, codfish, and numerous other odoriferous specimens of the grocer's stock, it is sold at five cents a quart. A sample of this milk which I examined contained about three-fourths per cent. cream, was acid in reaction, bluish in color, had a disagreeable odor, and a specific gravity of 1.026, so that it must have been watered as well as skimmed, as the removal of the cream of course raises the specific gravity. This awful compound is fed to babies quite largely in St. Louis, and no doubt in other large cities also, and must take an important place among the causes of gastric disturbances among infants. Our safest plan is to order the milk we use from one of the three or four large companies. The chances of getting poor milk are thereby reduced to a minimum, and if it is sterilized at once, no trouble will be experienced.

Our patients' parents should at least be warned about this corner-grocery milk. The small dairies that abound in the outlying districts of the city are not to be trusted. They all possess a large "swill wagon," although, of course, none of their owners will admit that they ever feed the cows on brewery grains, better known as swill.

Considered from a clinical stand-point, infantile diarrhœas may be divided into four classes: First, the simple diarrhœa, that which is caused by intestinal irritation only; second, the inflammatory diarrhœa, due to entero-colitis, or, more rarely, either enteritis or colitis alone; third, the colliquative diarrhœa of cholera infantum; and fourth, the symptomatic diarrhœa which occurs with varying degrees of severity in almost all acute diseases, as well as in the minor ailments of childhood. Simple diarrhœa is due to the presence in the intestine of irritation in the form of fermenting or indigestible material. Its diagnosis and treatment present no difficulty. The catharsis is a conservative action on the part of nature, for the purpose of expelling from the economy useless or dangerous material. It is characterized by a discharge which differs from the normal in fluidity and frequency, and contains some partially digested matters, together with more or less flatus.

It is usually brought to a termination by a few doses of "rhubarb and soda." I cannot speak in too high praise of this simple mixture of our grandfathers. The rhubarb, as is well known, combines tonic and astringent as well as laxative principles, the former asserting itself after the latter has had its effect, and for this reason the rhubarb is the remedy *par excellence* for this condition, in com-

bination with the alkaline soda and a carminative, usually cinnamon, or, perhaps better, a few drops of an alcoholic solution of menthol. By gently stimulating the action of the bowels it aids nature in relieving itself of the cause of the trouble and does not leave the intestines in a relaxed condition. The well-known tendency of neurotic children, as well as of all very young infants, to suffer from convulsions directly after the sudden checking of a diarrhœa should always be borne in mind. It is unwise as well as unnecessary to check this form of diarrhœa at once. A dose of bismuth or paregoric would simply shut up in the bowels a mass of fermenting material much better out of them. In four of the cases which form the basis of this paper a simple diarrhœa was changed into a severe type of enteritis by "home treatment" consisting of paregoric, or what amounts to the same thing, "soothing syrup."

The victim of entero-colitis presents a very different picture. Here we have the infant suffering acutely from abdominal pains, the belly is tumid and tender. The child's appetite is lost, it loses flesh and strength progressively, and has from five to twenty movements of the bowels a day. The fæcal matter may be from a pale greenish to a grass-green color, or more or less blood-stained. It usually has a very foul odor. In severe cases which assume the dysenteric type and which are pathologically very similar to dysentery, the discharges consist largely of a watery, bloody mucus. In this disease there is always some rise of temperature, particularly in its earlier stages. The progressive emaciation becomes very marked when the disease assumes a chronic form. I am convinced that the cause of very many of these cases is the withholding of water from the thirsty infant. My attention was first directed to this point several years ago by Dr. Clarke, of Oswego, N. Y., and my experience with sick children has confirmed his views. Of course decomposing as well as improper foods, together with foul air, play an important part in its causation; but the importance of the deprivation of water as a cause has been too often overlooked. When a child drinks milk or any fluid food because it is thirsty, and not because it is hungry, it inevitably drinks too much. Its digestive apparatus is flooded with milk, which of course curdles rapidly, and the stomach has more than it can attend to. The result is simple and prompt. There is felt in that organ a greater or lesser amount of sour fermenting stuff, which makes the baby cross and feverish and thirsty. Its thirst is again quenched —not with cool water—but with another bottle of milk, which it takes eagerly enough, but which simply adds fuel to the fire and makes a bad matter worse. The intestines are soon filled with this fermenting mass, and the result is a simple diarrhœa.

The milk is copiously supplied to the child, however, and the simple diarrhœa soon runs into an entero-colitis, and perhaps the child dies from exhaustion or in a convulsion, while the parents, and possibly the doctor too, talk about a mysterious visitation of cholera infantum—most convenient and most misused of terms. I have made it routine practice to tell mothers to give their children all the water they want, and particularly in hot weather to always give the baby a drink of water before feeding it. Then the child will take milk to satisfy its hunger only, and will not drink too much of it. Having already taxed your patience with my remarks on feeding and the causes of entero-colitis, which, however, here as in all children's diseases, are by far the more important matter, my remarks on treatment will be quite brief, and in this connection allow me to say that my experience has been strongly confirmatory of the statements made by our colleague, Dr. Hendrix, in his paper read before this Society in June of last year, in which he spoke highly of the value of water in the treatment of diarrhœa in infants. The child that has a profuse diarrhœa absolutely needs water. There is an actual lessening of the total amount of fluids in the body caused by the serous flow from the bowel. Water never makes a diarrhœa worse. On the contrary, by flushing the kidneys and by furnishing fluid for the general interstitial circulation it lessens the morbid process by stimulating normal tissue-metamorphosis and thus increases the general vitality of the patient. In regard to each case it is necessary to find out first and chiefly about the diet of the child in answer to the questions, "What?" "How often?" and "How much?" Our one hundred and eight cases of entero-colitis presented about this history: First, a harmful diet or deprivation of water, or both, then a simple diarrhœa occurred, followed rapidly by the inflammatory diarrhœa of the disease.

Their treatment may be divided into three parts: First, the regulation of food and drink; second, the disinfecting treatment, including sometimes the high injection per rectum of large amounts of sterilized water; third, the opium and astringent treatment.

The regulation of food consisted usually in prescribing small amounts of the milk-and-cream food referred to above, with plenty of water. Small doses of calomel at short intervals for two days will often change the character of a foul, green, watery discharge to a much more normal color and consistence, and put your patients in a condition in which astringents may be given. Rhubarb and all resin-bearing purgatives must be carefully avoided when any inflammation exists. Dysenteric conditions are best treated by frequent small doses of magnesium sulphate. The rule of action in these cases, as in all the diseases of children, must be to give the smallest dose that will do the work, and the indication is to give the stomach and bowels rest by removing from them the irritation caused by the presence of fermenting matters and the products of decomposition and inflammation. To accomplish this we must, as much as possible, disinfect the contents of the alimentary canal, as well as remove them. Thanks to some of the recent additions to our list of drugs, it seems now to be possible to do this in many cases. To that end the diet as above is ordered, or, if the child is vomiting severely, no food at all is allowed for two days, and calomel, gr. $\frac{1}{8}$ to $\frac{1}{10}$ (this for a child of six months) given every hour until five doses are given, and these doses repeated next day, using stimulants as indicated. On the third day, if the green diarrhœa continues, salol, gr. 3 to gr. 5, may be given three times a day, laudanum gt. $\frac{1}{4}$ being added if severe pain exists. We have employed this treatment in seventeen cases, nine of which recovered rapidly, five were lost track of, and three did not do well. If the seat of the trouble is in the large intestine, the action of the salol does not reach it, and in these cases large enemata of sterilized, rather hot, water were given. A large, soft-rubber catheter was used, and it was gently inserted, injecting the fluid meanwhile, for its whole length. In two of these cases the improvement was very marked. The third case, which had been poisoned with brandy by its mother, died the day after the high injection was practised, although the enema relieved it of its colicky pain and tenesmus. If this general line of treatment is followed, you will be pleased to find, in many quite severe cases, that after the small doses of calomel have been taken for two days, if the directions as to food and drink are followed, the entero-colitis has about disappeared, under which conditions we have remaining a case of simple diarrhœa, which needs a few doses of the rhubarb and soda, to each of which from one-half to a drop of the tincture of nux vomica has been added, to effect the cure.

Bismuth or chalk mixture is very useful when the diarrhœa shows a tendency to become chronic, and should both be used in large doses in order to produce positive effects.

Just as some of our professional brethren make a practice of calling every severe case of tonsillitis, for obvious reasons, diphtheria, so do many medical men call most cases of entero-colitis in children cholera infantum, for possibly the same reasons. Cholera infantum is a rare disease; true "inflammation of the bowels" is only too commonly met with. Among two hundred and fifty cases

of diarrhœa at the Post-graduate School, within a year, excluding the "symptomatic" variety, we had only three cases of cholera infantum, properly so called.

This is not the time or place to speak of the differential diagnosis. Suffice it to say that the clinical pictures of the two diseases are as unlike as they well can be, and the confusion of the names is gross carelessness, if it is not something worse.

## VILLOUS TUMOR OF THE RECTUM.

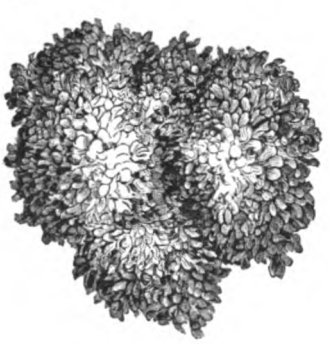
By GEORGE J. COOK, M.D.,

PRESIDENT OF THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION, CONSULTING SURGEON FOR DISEASES OF THE RECTUM TO THE INDIANAPOLIS CITY HOSPITAL AND INDIANAPOLIS CITY DISPENSARY, ETC.

On December 28, 1887, Dr. Cline, of this city, called me to see Mrs. S——, forty years of age, formerly robust and healthy, the mother of several children, and still menstruating. About five years previous she began to have, at times, some pain in the rectum and sacral region, dull and aching in character, and noticed occasionally a free discharge of mucus. These symptoms of rectal disease gradually increased until the pain became almost constant during the daytime, when she was up attending to her household duties, and the discharge of mucus was of daily occurrence. During the previous six months she had been losing flesh and strength rapidly, and now was confined to her bed most of the time, on account of general weakness and the distress in the rectum when in the upright position.

For two months past a tumor would present at the anus while straining at stool, but never entirely prolapsed, and occasionally some blood was lost. There was one natural passage from the bowels daily; but several times a day a large quantity of thin mucus would pass, sometimes a half pint or more at once. Her appetite was poor, could take but little food, and her skin was pale and waxy in appearance. Her history and appearance suggested some form of malignant disease.

On digital examination I recognized a tumor resting in the rectal pouch, well above the internal sphincter muscle. It was different from anything I had ever before felt in the rectum; so slippery that it was with difficulty held beneath the finger for examination, of a spongy consistence, with no induration, and firmly attached to the posterior rectal wall.



Tumor Removed.

When the patient was placed under an anæsthetic and the sphincters dilated, the tumor was easily drawn outside; it was the size of a large hen's egg, of a bright arterial color, had no pedicle, but grew from the gut wall by a broad base. A fold of mucous membrane was dragged down to allow it to come outside the anus. There was some thickening of the fibrous tissue at the base, and from this sprang long villous processes, which composed the bulk of the tumor. Each one of these increased in size from the base toward the free extremity, giving the ends a clubbed appearance.

The outline of the tumor was very distinct. There was no surrounding zone of congested or inflamed membrane, but the healthy tissue came up to the outer row of villi. The contrast in color was marked; the surrounding membrane was pale, owing to the great debility of the patient, and the tumor was of a bright arterial hue.

It was removed by passing a double ligature through the fold of mucous membrane above it, tying, then cutting off with the knife. The ligature came off after a few days, and the patient made a rapid recovery, soon becoming strong and more fleshy than ever before in her life.

I quote the following from the chapter on "Villous Tumors of the Rectum" in the latest edition of Allingham on "Diseases of the Rectum," issued last year:

"This is a rare but interesting disease. Mr. Quain in his work gives the details of only two cases that had fallen under his observation. I have seen eighteen examples of this growth; eleven in my own practice, three in St. Mark's Hospital, under the care of my late colleague Mr. Gowlland, one in the practice of my colleague Mr. Alfred Cooper, and three under Mr. Goodsall's care; added to these I only find reported two by Mr. Symes, one each by Messrs. Cripps, Gosselin, Van Buren, and Bryant—twenty-four in all."

It is indeed a rare surgical disease of which only twenty-four examples can be found recorded in surgical literature, this case making the twenty-fifth.

Some of these tumors are described as having distinct true pedicles; others broad pedicles composed of a fold of mucous membrane dragged down by the tumor; and others again, like this one, attached to the rectal wall by a broad base. Those having a true pedicle seem to be composed mostly of fibrous tissue, with the surface covered with villous processes, while those attached by a broad base are formed almost entirely by the elongated processes, thus differing in structure according to the varying proportion of the different elements. Hence we find the authors differing in their descriptions. One says they have a soft, velvety, villous feel, and a want of the solidity and firmness which is felt in large polypi; another says they have the feel of a large warty polypus, with cauliflower surface; and still another says they have the feel of a huge warty growth.

This tumor has been found only in adults, and the majority of the patients have been over fifty years of age. The prominent symptom is the discharge from the rectum of large quantities of thin mucus, increasing in amount as the tumor increases in size. This mucus must come from the enlarged villi, since, as in this case, the discharge immediately stopped when the tumor was removed, and, the surrounding mucous membrane was very pale and could not in that condition have secreted an excess of mucus. In many of the cases blood was lost in large quantities. Quain calls this the "peculiar bleeding tumor of the rectum." When any of the villi are broken, free bleeding will certainly occur; and when there is prolapse of the tumor during stool, and it is grasped firmly by the sphincter, such a result could scarcely be avoided, though the villi are not easily broken down or torn. There is a gradual loss of flesh and strength, and this without the loss of blood. In the present case the loss of strength and flesh began long before any blood passed away; so the general prostration must be attributed largely to the loss of mucus, which may amount to several pints daily. The tumor in time will be forced down and prolapse at stool, and when seen by the surgeon need not be mistaken for any other form of growth in the rectum.

Most authors describe these tumors as innocent in character, and seldom recurring after thorough removal; but Mr. Allingham states that they may recur as malignant growths, he having seen three cases in which epithelioma replaced the villous tumor.

18 West Ohio Street.

A Medical College in Chicago has been sued in the sum of $5,000 for refusing a ticket of attendance to a lady medical student. The college claimed that she did not apply early enough in the season.

## APPARATUS FOR STERILIZING MILK.[1]

By T. M. CHEESMAN, M.D.,

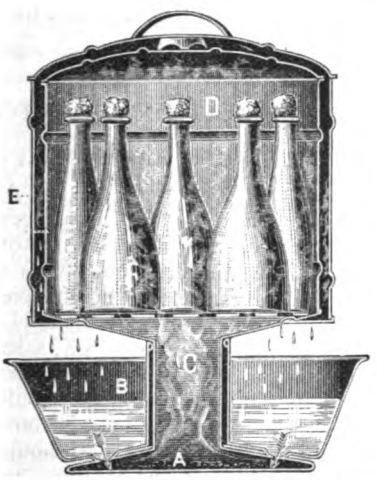
ASSISTANT IN BACTERIOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE necessity for sterilizing infant food, more particularly during the hot seasons, is my reason for drawing your attention to a sterilizing apparatus, which is known as the "Arnold Steam Sterilizer." It was introduced into the laboratory of the Alumni Association of the College of Physicians and Surgeons by Dr. Prudden, for sterilizing culture media, and its recommendation comes from a thorough test of its merits.

To Professor Soxhlet is due the credit of first sterilizing milk for infant feeding, and to Dr. A. Caillé the credit of introducing the practice to the profession in this country; but the apparatus here shown presents certain advantages over that which is recommended by them.

The cooker consists of (1) a flat shallow boiler, holding but a small amount of water, and therefore requiring but a minimum amount of heat to produce steam; (2) a reservoir, which constantly feeds the boiler and causes steam to be formed continuously; (3) the steam chest or receiving vessel; and (4) a hood, enclosing a space between itself and the receiver, which is constantly sup-

Hood.



A, Boiler. B, Reservoir. D, Steam Chest or Receiver.

plied with escaped steam, a device which causes a temperature once reached to be maintained so long as the heat is unchanged.

Sterilization is accomplished by bringing the object to be sterilized to the temperature of live steam, and maintaining it at that temperature for about forty-five minutes. Boiling for the same length of time, in a vessel the sides of which are exposed to the air, is not efficient, as the temperature in different parts of the vessel is found to vary considerably. This is the main objection to Soxhlet's apparatus, the principle being that of a water-bath. While in the cooker, we have a steam-bath, in which variation of the temperature is prevented.

Numerous tests have shown that with a single Bunsen burner, and ordinary gas pressure, the temperature of 100° C. is reached, in all parts of the receiving vessel, in less than ten minutes. The time required to raise the fluid to be sterilized to the same temperature is found to be directly proportional to its bulk. So that less time is required when the food is in divided quantities. When the temperature of 100° C. is reached, sterilization has commenced, and should be continued for the time specified, forty-five minutes, which time is necessary on account of the great resistance of the spores.

As a sterilizer, the cooker presents these principal advantages: 1, its effectiveness in sterilizing; 2, economy, both of time and fuel; and 3, great convenience, on account of its portability.

The recommendations to any who might use it are as follows:

That the food be prepared as it is to be administered, and that the quantity required for twelve or twenty-four hours' feeding be distributed in eight-ounce flasks or nursing bottles, providing one such bottle for each feeding, so that no unnecessary exposure or transference shall be had. In filling the bottles a funnel should always be used to keep the necks clean, and the fluid should be a full inch below the neck. The bottles should be plugged with cotton, extending well down into the neck, any impurities which this may contain, in the form of moulds or bacteria, being destroyed by the same process which sterilizes the food. The bottles are now placed in the cold receiving-vessel (to prevent breakage) and heat is applied by means of gas, or a kerosene or coal stove. To insure a complete sterilization, heat should be maintained altogether for one and a quarter hour.

Food thus prepared can be kept at ordinary temperatures for an indefinite period, doing away entirely with the use of an ice-pail or refrigerator for keeping the milk sweet.

When the food is to be given the bottle is to be well shaken to mix in the cream, the cotton plug is removed, and the nipple applied to the bottle at once. In cases where it may be necessary to administer food at a higher temperature, the bottle is stood in warm water, as is customary. In regard to the nipples, it is not practical to sterilize them, as heat destroys the rubber, but they can be thoroughly cleansed by the ordinary methods.

## TREATMENT OF DIABETES.

By JOSEPH S. CARREAU, M.D.,

NEW YORK.

DUJARDIN-BEAUMETZ, at a meeting of the Académie de Médicine, March, 1888, praised the happy effects of antipyrine in certain cases of diabetes, especially when the two symptoms, polyuria and nervous irritation, predominated. Henri Huchard, at the Société de Thérapeutique, Feb ruary, 1888, said that he had employed antipyrine in a case of symptomatic polyuria resulting from meningo-myelitis, with good effects. He gave from four to six grammes daily, and the quantity of urine was brought down from thirty-six litres to four. He also reported a case of diabetes, where he noticed, in a few days, the sugar diminish from 735 to 271 grammes a day under the use of antipyrine—two to six grammes daily. He also said that the prolonged administration of antipyrine, in his own experience, has never been followed by albuminuria.

M. Panas reported two cases to the Académie de Médicine, April, 1889, where great relief followed the administration of antipyrine. A man aged thirty-eight, passing forty-nine grammes of sugar in twenty-four hours, by taking two to three grammes daily during six days, had all traces of sugar in his urine removed. A woman, aged seventy-three, by taking three grammes daily, for a few days, also received similar benefit.

The following are some cases in which I employed antipyrine.

CASE I.—Mr. C——, aged sixty-two, diabetes of long standing. From 1885 to 1888 had been under various forms of treatment in different countries; the sugar had been reduced in quantity, but had never entirely disappeared. In March, 1888, he began the treatment by antipyrine, ten grains four times daily, with strict diet, to be continued for three days. On the fourth day no improvement was found; then ten grains were ordered six times in twenty-four hours. At the end of these last three

days, the urine was decreased in quantity, the specific gravity was lower, and the quantity of sugar was less. The pulse being feeble and rapid, the antipyrine was decreased to ten grains three times a day. At the end of six days more the sugar had entirely disappeared, the quantity of the urine had also diminished from nine quarts to two, and all the other symptoms had also improved. The antipyrine was discontinued, and the patient was placed under tonic treatment and strict diet. Since then he has had two more attacks, which were subdued by the same treatment, the first lasting seventeen days, the second only eleven. Since March, 1888, the patient's health has been better, he has gained flesh and strength, and has been able to take some outdoor exercise.

CASE II.—Mrs. A——, aged thirty-eight, a thin and nervous woman, mother of three living children, having had a miscarriage, which occurred ten years previously. She complained of excessive thirst, and passed six quarts of urine in twenty-four hours, specific gravity 1.032 with traces of sugar. She had a chronic pelvic abscess, with fistulous tracts opening into the vagina. She was placed under strict diet, and took from forty to eighty grains of antipyrine daily, during sixteen days, after which the quantity of urine became normal, all traces of sugar had disappeared, and the characteristic symptoms had improved. She was placed under diet and tonic treatment. She has been able to work ever since, supporting her three children by her labor.

CASE III.—Mr. B——, aged forty-eight, had sciatica for ten years; has to urinate every half hour, passing in twenty-four hours from eight to ten quarts of urine, specific gravity 1.030, loaded with sugar. He was ordered fifteen grains antipyrine four times daily for three days. Slight improvement followed. On the fourth day the same dose was ordered six times in twenty-four hours for three days more. At the end of this period the pain had stopped, the quantity of urine was brought down to two quarts, and no sugar was detected by Trommer's test. Antipyrine was discontinued; iron and cod-liver oil with strict diet was ordered. In January, 1889, he had another attack of sciatica and glycosuria, which was subdued in ten days by the above treatment.

## MACERATED FŒTUS AS A COMPLICATION OF LABOR.

BY SARA E. POST, M.D.,

NEW YORK.

THE case was that of a primipara. The date of conception was uncertain, but quickening occurred, I was told, about October 10, 1888. About the middle of January the mother fell, so as to inflict a wound upon the knee, of which the scar still remains. Pregnancy, however, appeared to progress normally until about the middle of February, when I was called in because the movements of the child had apparently ceased. The mother could not say how long previously such movements had last been shown. I was unable to detect life, but found nothing peculiar in the contour of the tumor. As the mother remained well the condition was not interfered with, and labor came on in March, at about the calculated time. There had been some loss of fluid the night previously, but, it being the first child, the young mother could not tell whether it had been more than the escape of urine. The quantity at least was not large. At the time I was summoned, labor was progressing. A membranous bag presented, smooth, its contents plainly fluid. The bag itself, however, had a peculiar feel of leathery thickness unlike that of the amniotic sac. The cervix dilated and this bag came down so as to distend the vagina. Contractions then became feeble and labor was delayed for a number of hours. My first suggestion was that I was dealing with a condition of thickened membranes, as no amniotic fluid whatever had been lost in my presence. Upon this hypothesis I was considering the question of puncture, and had exposed the bag of fluids for the purpose, when I found it muscular or "fleshy" in appearance, causing me to abandon this first view. It then seemed to me more probable that the membranes had ruptured the night previously, and that a monstrosity of some description had presented. Upon this supposition I asked for counsel. On account of this request, or for some other reason, labor recommenced, the mass descended, and within it some loose cranial bones, so that its character became soon apparent, and the labor was completed without difficulty. When born, the fœtus was found of about eight months' development, the skin macerated over the whole body as well as the scalp. The brain was replaced by a reddish liquid of the consistency of pea-soup, in which the bones of the cranium floated. Even the base of the skull was loosely articulated, and the whole head had become the fleshy fluid-containing bag which, on account of the absence of hair and epidermis, I had failed to recognize. There was no odor about the specimen, and the abdominal and thoracic contents were not noticeably softened.

I cannot think that this is a very common complication of labor, as I have mentioned it to several physicians with large obstetric practice who had never met such a case. I relate it particularly for the benefit of other young practitioners, and simply to draw attention to the fact of possible misapprehension connected with it. Had I gone on to rupture the supposed bag of waters the result would not have been nice.

## THE PREPARATION OF CATGUT.

BY JOHN C. SCHAPPS, M.D.,

BROOKLYN, N. Y.

FOR the last four or five months I have been making use of the following simple, and thus far satisfactory, process in preparing catgut. The gut, in as long pieces as can be procured without knots, is placed, with sufficient ether to cover it, in a wide-mouthed, glass-stoppered bottle. What is known as a six-ounce, German XX, saltmouth is an economical size, as the internal diameter just permits the ordinary coil to lie flat. The stopper should, of course, be a very perfect fit. The ether soon becomes discolored and gives off a strong animal odor, and should be changed every day or two until it remains colorless and has no impure scent. The catgut in a few days is nearly white, and has a peculiarly clean feel. The fatty and other soluble organic matter being removed, it is probably now perfectly aseptic. Certainly aqueous germicidal solutions can easily penetrate it. It is, however, my custom to wind each piece upon a glass spool, and keep it in a small bottle containing an ethereal solution of mercuric bichloride, one to one thousand. By means of a needle, the end of the catgut is passed through the cork, which need not be removed until the spool is empty. The tensile strength of the catgut appears in no way affected by this process, though it rapidly loses its stiffness in water.

As yet, with one exception, I have not had a drop of pus in any wound (including those of knee-joint excision and amputation of the breast) in which catgut thus prepared was used. This exception was probably due to imperfect scraping of an old suppurating cavity. It is, however, to be stated that I have not experimented with the thickest kinds of catgut; but if ether will not permeate them it will be hard to find anything that will. The fact that the danger of catgut lies in the fatty matter, in which the microbes are ambushed beyond the reach of watery solutions, has led to the recent movement toward abandoning the use of this material altogether. These points are well expressed in an article by Dr. George R. Fowler, in the December number of the *Annals of Surgery*. But if a more extended experience shows that in ether we have a remedy, catgut is for many reasons to be preferred, as suture or ligature, to silk or linen thread.

I have only recently learned that it has been the custom

at the Methodist Episcopal and St. Mary's Hospitals, in this city, to employ juniper oil as a sterilizing agent, and then to use ether to wash out the excess of oil. But the ether process appears to me to be more direct, simple, and thorough.

486 Bedford Avenue.

## Progress of Medical Science.

The Use and Abuse of Massage.—At a recent meeting of the British Gynecological Society, Dr. Macnaughton Jones gave the Fellows his views on the *rôle* of massage in gynecological practice, and at the following meeting a lively discussion took place which brought out many points of interest and instruction. Although it was by no means the intention of the author to run down a method of treatment which he evidently holds in great esteem, his paper contained certain observations on the subject of the degenerate way in which massage is at present carried out in the hands of the masseurs and masseuses (whose name is legion), and these served as a text upon which the opponents of massage preached a very stirring sermon. Looked at from a disinterested point of view, massage is a practice the value of which is certified by a hoary antiquity, and is doubtless of service in a large class of cases which are more or less obnoxious to other methods of treatment. Nothing, however, that we know of the practice can justify the extraordinary vogue which it at present enjoys, and the high-flown expressions upon which it is sought to build up a pseudo-scientific procedure are little else than a cloak for one's ignorance on the subject. Leaving on one side, for the present, the precise indications for massage and the method in which it should be applied, the great and general ground of complaint is that the method has fallen into unscrupulous and unskilful hands, with detriment to the interests of the patients and to the method itself, which is in serious danger of falling into disrepute in consequence of the doubtful way in which it is carried out at certain institutions and by certain persons. The only indications for massage, according to one of the speakers, is that the patient shall have a thin body and a fat purse, and the whole treatment is more or less a process of "milking!" The application of massage to disease of the internal pelvic organs, as exemplified in "massage of the uterus," came in for severe strictures on all hands. As described by the author of the paper, the performance would seem to bear a singular resemblance to masturbation, and one can understand and sympathize with the reluctance evinced by many medical men to being parties to any such proceeding; more especially as one is aware of the fact that for purposes of treatment, the patient is confided to persons of whose accomplishments and morality we have little or no guarantee. It is possible, as urged by the president, that good results may be obtained thereby, notwithstanding that anatomical considerations would seem to negative the idea of the possibility of any efficient massage of that much-tried organ, but we are certainly justified in asking that the treatment shall only be carried out under the direct superintendence of a medical man, so as to avoid any risk of improper practices. The author of the paper seemed to be much disappointed at having elicited a discussion so foreign to his intentions, but there can be no doubt that it is high time the profession, as a body, took official cognizance of the harm that is being done by indiscriminate employment of this particular method of treatment by persons whose only claim to practise as such is based on a three months' course of lectures by this or that person, who has arrogated unto himself the proud title of professor of the noble art of massage. We are informed that the applications of marauding masseurs and masseuses for employment has come to be a veritable tribulation to men who are credited with being in a position to recommend patients. The only way to put a check upon the degradation complained of would be for the medical societies to discuss the matter, and to bring the pressure of public and professional opinion to bear upon the persons, many of whom belong to the profession, whose conduct conduces to the practices in question. Gynecologists are not more interested than practitioners in other departments in taking the matter up, and, perhaps, now that the ice has been broken, the subject may be considered worthy of attention at the hands of the representatives of the profession who weekly meet and assemble together, as they flatter themselves, for the advancement of medical science. —*The Hospital Gazette.*

The Treatment of Whooping-cough.—Dr. R. Daniel writes to the *British Medical Journal* that in a recent epidemic of whooping-cough he had an opportunity of giving many drugs a trial, and of noting their efficacy. Glycerine of carbolic acid was administered in a large number of cases, but was by no means universally successful in checking the disease. It was most beneficial (1) in children under one year; (2) in uncomplicated cases; (3) where secretion was excessive. It sometimes had a marvellous effect in controlling spasm, and its good was intensified by carbolic vapor or a spray in the sick room. The dose invariably given was ½ minim every three hours to children under one year, that amount being increased to 1½ minim for children of two years, and so on in proportion. In the majority of cases treated he found the best results from a mixture of tincture of belladonna (in full doses), vin. ipecac., and glycerine, given every two or three hours, according to intensity and frequency of the paroxysms. With Dr. Collyns, he preferred to give a dose of potass. bromid. at bedtime, instead of with the day mixture. A hot bath, too, at night, had often a most soothing effect, and formed a very useful adjunct to medicinal treatment. The employment of compresses to the spine during the day also proved beneficial. Diet, regular and nourishing, he found of the greatest importance. Sickness is often exceedingly troublesome, and in such cases a peptonized-milk diet was of great value. Dr. R. Guaita, medical director of the Children's Hospital at Milan, confirms (*British Medical Journal*) the value which has been attributed to antipyrin as a remedy in whooping-cough. During an epidemic at Milan, last summer, he used it in 22 cases, 12 of which were of great severity, with the result that in every instance the disease was completely cured in from four to five weeks. No complication of any kind occurred. The age of the patients varied from five months to nine years, with the exception of one who was over twenty. In all the cases the symptoms subsided or became more marked according as antipyrin was given or withheld. Dr. Guaita thinks that the good effect of the drug is due partly to its inhibitory action on the nervous system, and partly to its antiseptic properties; he calls it the "sovereign remedy, for the present at least, in whooping-cough." He gives twenty-five centigrammes of antipyrin in twenty-five grammes of syrup of orange peel, with an equal quantity of distilled water, in four doses in twenty-four hours, increasing the dose of antipyrin to one or one and a half gramme, according to the indications. If the cough causes vomiting he finds a small quantity of hydrochlorate of cocaine given with the antipyrin most useful.

Improved Method of Amputation of the Penis.—The most unpleasant symptom following amputation of the penis is the funnel-like retraction of the urethra, which causes the patient endless discomfort. Dr. Assaky overcomes this by dissecting the pars spongiosa of the urethra from the penis, for about an inch beyond the superficial incision. Then the corpora cavernosa of the penis are cut through from below, leaving about half an inch of the urethra protruding beyond. The tunica albuginea and the skin are then brought over the stump of the pars cavernosa and stitched around the protruding urethra. This will retract to some extent, leaving a very natural looking meatus.—*Centralblatt für Chirurgie.*

## THE NORMAL POSTURE IN LABOR.

THE observations and records of travellers, ethnologists, and physicians show that women of various races, during labor, assume very different postures. The precise posture seems to be determined partly by instinct, but largely, in many cases, by custom. Instinct, among civilized races, does not seem to be a very certain guide, if one may trust the reports of Schütz and Von Baren. These physicians took a young, healthy woman, pregnant for the first time, quite ignorant of the process of labor, and totally uninstructed as to what she should do during its continuance. Such a woman was placed entirely alone in a room containing chairs, stools, sofas, cushions, beds, etc., with every opportunity to use any, all, or none of them, as she might desire, and to assume any position or positions she might wish. On being watched, it was observed that she behaved, in each of the experiments, exactly as a man or any other person would do when suffering from a severe attack of colic. Finding no relief in one position, she would get into another, and so on; continually changing her posture, simply following the instinct of seeking relief from pain. Of 50 such experiments recorded by Schütz, "32 (over half) occupied abnormal positions; 14 standing, 16 crouching or squatting, 2 kneeling.' Of 100 other such cases, cited by Dr. Cohen v. Baeren, of Posen, 50 "occurred in unusual positions: 30 standing, 18 crouching or squatting, and 2 kneeling" ("Transactions American Gynecological Society," 1880, p. 176). In one such experiment by Naegele, "the girl took all possible positions, and was finally delivered tossing about on the bed."

Some years ago Dr. Engelmann, as the result of his studies as to the normal posture in labor, concluded that:

1. In the ordinary labor case, which is a purely mechanical process, the patient should be given greater liberty and should be permitted to follow the dictates of her instinct in regard to her movements, more freely than is now customary.

2. In the earlier stages of labor the parturient must be guided in her actions and in the position assumed by her own comfort and by the dictates of her instinct.

3. The recumbent position retards labor and is inimical to easy, safe, and rapid delivery.

4. In ordinary labor cases the expulsion of the child should be expected in an inclined position: kneeling, squatting, or recumbent, in bed, on the chair, or lap, as is done by the great majority of uncivilized people.

5. Of these positions, the semi-recumbent is the most serviceable, and should be adopted as the obstetric position in all ordinary labor cases; it is preferable to the kneeling or squatting.

Many years ago American physicians were taught to deliver the woman while lying on the left side; but for a long time this practice has been given up, and the rule generally is now to allow the labor to occur with the woman lying on the back.

Recently there has been considerable said again in favor of the left-side posture. Dr. A. F. A. King, of Washington, has discussed the subject exhaustively in the *American Journal of Obstetrics*, No. 4, 1889.

Dr. King is convinced that there is no one posture which is best, and that a change in position to meet various indications is the most important element. He cites the case of a woman who, in obedience to her physician, and contrary to her own expressed, instinctive wish, was kept in bed during labor for *sixty hours;* at the end of this prolonged dole of agony, no progress being apparent, her request was acceded to; she was allowed to sit up, and immediate delivery followed. It may be added that this woman was sixty years of age, and had previously given birth to seventeen children! In three other cases, when it was thought necessary to apply forceps, a similar change of posture secured rapid delivery without difficulty, and without instrumental aid.

The exact changes and final position of the woman should be determined by the obstetrician after a careful examination of the case. He concludes:

1. There is no *one* posture that can be normal for the parturient woman.

2. The continued maintenance of one posture wastes and exhausts the forces of labor, interferes with the normal mechanism, and adds to the duration and intensity of the woman's suffering.

3. Exactly opposite results are produced by proper changes of posture.

4. The indications for change are: Instinctive desire for it; arrest of the mechanism of labor; emotional discontent, peevishness, and despair.

5. The normal mechanism of labor being at present imperfectly understood, and the influence of different postures upon this mechanism, during the several stages of the several "positions" of the several "presentations" being unknown, the selection of given postures for given conditions cannot be defined without further study.

We must be permitted to conclude that some of these conclusions, if true, reflect little credit upon the modern obstetric art. If "the normal mechanism of labor is still imperfectly understood," it argues extraordinary dulness on the part of physicians who have been delivering babies since medical science began. Furthermore, as over ninety per cent. of labors are normal and take place in almost precisely the same way, it seems as though obstetricians should be able to tell the woman what would, with the greatest probability, be the proper position for her to adopt. Professor King, it seems, would leave the unhappy parturient uncertain whether she should squat like a Kaffir, hang from a rope like an Apache, kneel like a Mexican, hang to a pole like a Blackfoot squaw, stand like the Ceramites and ladies of the Nile, lie on the stomach like the Creeks, on the side like the English, or

on the back like the American. It seems but fair that modern obstetrics should give parturient ladies less postural latitude than is implied in Dr. King's conclusions, which, we take it, are held to apply to the second stage of labor.

### "HALF-FILLED HOSPITALS."

SOME correspondence has recently taken place in one of the leading daily papers relative to hospital management. It began with an editorial with the caption of this article, and was followed by a letter from the general agent of the Hospital Saturday and Sunday Association. The charge made in the editorial was, in general, that there are in Brooklyn and New York many empty hospital-beds, while the sick poor are suffering from lack of hospital-care; that the managers of these institutions do not admit these proper objects of their charity, because either of their inability to pay or the disagreeable nature of their illness. The charge is still further particularized in being applied to the hospitals directly under the charge of the different religious denominations.

We cannot but believe that the writer is misinformed as to the true facts in the case. He may, as many do, make the mistake of not recognizing the distinction between a hospital for acute diseases and a home for convalescents, or for chronic maladies. Application is often made for the admission to hospital of a chronic case which has worn out a family at home, and disappointment is felt that the patient is refused admittance. Such refusal is justly based upon two reasons. In the first place, it is the obvious duty of any charitable agency to labor in that field where it can do the most good. The filling of the beds with such cases, generally susceptible of but slight improvement, prevents the reception of cases of acute illness or severe accident where a little timely aid may save a life. In the second place, a hospital is not, for therapeutic reasons, the place for such chronic cases to be treated. They need cheerful surroundings, and the avoidance of all depressing scenes. In a hospital these conditions cannot obtain, particularly in the larger ones, with an ambulance service where maimed and bleeding cases are being brought in at all hours of the day and night, and where deaths are constantly occurring.

It is greatly to the credit of our so-called denominational hospitals that religious belief is not made a test of entrance. You will find Jews in St. Francis Hospital, Catholics in St. Luke's, and Protestants at Mount Sinai, and, as far as we have observed, all are treated equally well.

The story related in the daily journal above alluded to is an exceptional case. It is, briefly, that a woman recently confined applied to an institution in Boston. She was refused admission because "they didn't take that class of cases," and finally was found dead on the docks with the corpse of the baby under her ragged shawl. This is, of course, a most deplorable case, but a wholesale indictment should not be based on it. It must be admitted that in this instance "some one had blundered." We venture to say that that thing would not have happened at any of our institutions in connection with the ambulance service. It is evident that an institution founded for the carrying on of certain lines of medical and surgical work cannot alter its scope at every application for admission. But what could be done, and what, we are happy to believe, is done here in New York, is to take charge of every applicant who comes in a condition of acute physical suffering. If the case is a proper one, it is kept. If this cannot, for any reason, be done, it is transferred to some city institution where it can be properly cared for. It is not told merely to "move on."

Relative to the charge that "there are a few well-endowed and amply maintained institutions that expend a large share of their revenues in keeping up appearances and are not doing the work which their open-handed patrons have placed it within their power to do," we can say nothing in the absence of more definite particulars. We can believe this possible, but do not think it probable. Anyone who knows much about our local institutions knows that the great annual problem is to make buckle and strap meet over the necessary expenditures, let alone keeping up useless appearances. The low current rates of interest have greatly lessened the sustaining power of endowment funds. To anticipate a remedy for the alleged state of affairs, we would recommend, as we have so often done, that medical men should be admitted to the hospital managing boards. We believe that material resources could be greatly conserved thereby, by a wiser and more discriminating expenditure.

### THE DEFICIENCIES OF OUR VITAL STATISTICS.

THE report of a special committee, composed of Drs. J. G. Truax, J. R. MacGregor, and Alfred L. Carroll, to the New York County Medical Association, discloses a fact which has long been known with regard to the deficiencies in our system of obtaining vital statistics, viz., that the birth-returns are very deficient.

The State law puts upon the parents or custodians of children the duty of reporting births, except only in five specified cities, of which New York and Brooklyn are two. In these cities the responsibility is put upon the physicians and the few registered midwives. The result is that, where no physician is called in at a birth, and no responsible midwife, the chances are that the birth will not be registered.

As a remedy, the committee recommend that the law be made uniform for all the cities, and that the responsibility of notification be placed on parents or custodians.

We should welcome any change which takes away an unwarranted responsibility imposed upon physicians; but it is not easy to see how the change would increase the accuracy of the returns.

### THE NOTIFICATION OF PHTHISIS PULMONALIS AS A CONTAGIOUS DISEASE.

THE Health Department of this city is studying with much care the problem of the prevention of phthisis through destruction of its infecting agent, the bacillus. It is, in particular, directing its efforts to the more crowded portions of the city, where the danger of infection is greatest. The exact mode of attack upon the bacillus has not, we believe, been fully decided upon, although some preliminary steps have been taken. The most serious question which has arisen, we take it, is as to the advisability of classing tuberculosis with the contagious diseases that are now reported to the Health Department, and requiring

that it be similarly reported. The advantages of this step would be that it would educate both physician and public to the view that phthisis is infectious, and would impress upon both the fact of the necessity of using disinfection in connection with its treatment.

On the other hand, it might needlessly alarm the public and perhaps add, unnecessarily, to the discomfort and suffering of the patients. We doubt very much, also, if the medical profession would co-operate heartily in notification, except as regards hospital and dispensary patients.

Despite some disadvantages, however, we believe that a trial at least of the notification plan might be made. In promulgating and practically enforcing the view that pulmonary phthisis is a contagious disease, however, most careful and explicit statements should be made as to what is meant by this contagiousness. It should be shown that the disease is not contagious in the popular sense at all, *i.e.*, communicated by contact, or the breath, but only by the medium of the sputum; also, that unlike syphilis and other infectious diseases, it cannot be communicated under any ordinary conditions, except to those who are predisposed by various constitutional and depressing agencies to its development.

## News of the Week.

Sir Morell Mackenzie.—A most elaborate banquet was given Sir Morell Mackenzie last week. Lord Randolph Churchill presided and many distinguished men were present.

A Banquet to Dr. Traill Green was tendered at Easton, on June 20th, by the County Medical Society. A large number of Easton physicians were present, as well as several gentlemen from Philadelphia. Dr. Green was born in 1813, and has practised medicine since 1836—fifty-three years.

Accident from the Electric Current.—A man living in St. Paul, Minn., accidentally received a severe shock of electricity which knocked him senseless for forty-eight hours. He has recovered, and says that the sensation on receiving the current was not painful.

Suicide of a Physician.—Dr. Waters, an aged physician of this city, recently committed suicide because, it is said, he was unable to get sufficient practice to support himself.

The Death of Dr. C. B. Radcliffe, of London, recently took place, in the sixty-seventh year of his age. Dr. Radcliffe was an original and voluminous contributor to physiological and pathological subjects.

Lactose as a Diuretic. — Professor Germain Sée asserts that lactose is a powerful diuretic and is the active diuretic principle in milk. It acts with certainty in cardiac dropsies and is the diuretic in such conditions. It does not relieve the cardiac dyspnœa, for which potassium iodide is needed. One hundred grammes a day may be given. *À propos* of this, we may cite a paragraph in the *Boston Medical and Surgical Journal* to the effect that milk-producers in New York State think they see a small measure of promised relief from the present depression of prices due to over-supply, in the development of the sugar-of-milk (*saccharum lactis*) manufacturing industry. Formerly consumers of the article in this country have depended entirely upon importations from Switzerland and Bavaria, and it is only lately, and in view of the increasing demand, that an attempt has been made to supply the market with a home-made product.

Dr. Stephen Wickes, of Orange, N. J., died on July 8th, aged seventy-six. Dr. Wickes was a man of fine education and unusual literary attainments. He edited the "Transactions of the Medical Society of New Jersey" from 1860 until 1882; also the old transactions of the Society from 1766 till 1858. He published "Topography of Orange," "Water Cure in Orange," "Memoirs of Thomas W. Blatchford, M.D.," of Troy; a memorial volume of the First Presbyterian Church, with which he was so long connected; "Living and Dying, their Physics and Psychics," "History of Medicine in New Jersey," "Sepulture: Its History, Methods, and Requisites," and "History of the Newark Mountains."

A Remarkable Epidemic of Pneumonia.—In the *Maritime Medical News* for May there is an account of an epidemic of pneumonia in Prince Edward Island. During the months of February and March no less than five hundred and forty-six cases occurred in the practice of twenty-six practitioners, and at the date of the report the disease was still very prevalent. As there are over fifty practitioners in the island, it is computed that the total number of cases is fully upward of one thousand. As the population of the island does not exceed one hundred and fifty thousand, the number attacked is relatively very great. It appears that in the majority of cases the pneumonia was attended by acute bronchial catarrh. The catarrhal complications, which in some cases also involved the larynx and middle ear, were more frequent in children and the aged. In the five hundred and forty-six cases reported there were only forty deaths, a decidedly low mortality.

Medical and Surgical Work at Roosevelt Hospital.—The annual report for 1888 contains some interesting medical and surgical statistics and is a great improvement on the average hospital reports. We learn that there were 56 cases of typhoid fever treated in the hospital, with seventeen and one-half per cent. of deaths; also 56 cases of lobar pneumonia, with 24 deaths, or forty-three per cent. We note the record of 5 laparotomies, 4 exploratory, with 4 deaths—not a very brilliant showing. There were 3 operations for typhlitis, with 2 deaths. On the other hand, there are 27 operations recorded for laparotomy for diseases of the reproductive organs, besides 4 vaginal hysterectomies, with but 4 deaths.

Professor T. G. Richardson has resigned from the faculty of Tulane University on account of ill-health. He has had an exceptionally long term of service—thirty-one years—fourteen years in the chair of anatomy and seventeen in that of surgery. In Germany, Professor Richardson would be given a jubilee.

Dr. R. J. Hall has resigned the Professorship of Anatomy in the College of Physicians and Surgeons on account of ill-health. This leaves two of our colleges without professors of anatomy.

A German Anthropological Congress will be held in Vienna, August 5th to 10th.

North Carolina Insane Asylum.—The daily papers contain reports of the trial of Dr. Grissam, for many years superintendent of the North Carolina Insane Asylum, on charges of cruelty and immorality. We trust that Dr. Grissam, who has long sustained an excellent reputation, will acquit himself of the painful accusations made against him.

A Recent Decision of the Surrogate has been made to the effect that, as a matter of law, the indulgence in the opium-habit, even though to excess, cannot be considered sufficient to establish want of testamentary capacity.

The Students of the Ambulance Corps of the New Orleans Charity Hospital have made their appearance in uniform. The outfit consists of a navy-blue suit, square-cut sack-coat with brass buttons, and a white cap.

They Want Clinical Facilities.—At a meeting of the students of the Medical School of Maine, held in Brunswick, June 24th, the following resolutions were formally adopted by the students:

*Whereas*, We, the students of the Medical School of Maine, unanimously believe that the benefits of the school are marred by the lack of clinical advantages, and for this reason many of the students are accustomed to leave the school at the end of the first or second year to finish their course in schools possessing greater clinical facilities; and

*Whereas*, The city of Portland presents by far the best advantages of any locality in the State, both clinical and in other respects;

*Resolved*, That we unanimously second the resolutions relative to the removal of the Maine Medical School adopted by the Maine Medical Association at their last session.

The students at Ann Arbor might read these resolutions with profit.

It may Lead to an Intestine War.—The daily papers announce that the latest trust that is forming in the West is the Castor-oil Trust. It appears that manufacturers are ready to take the final step and organize a trust combination with a capital stock of $250,000 to $500,000. The Castor-oil Trust will be an immensely profitable one. The price of the seed has been about $1.50 a bushel for years, while the price of the oil has been over 15 cents and as high as 16 cents, and not lower than 12 cents a pound. On the basis of 15 cents the crushers have a profit of 4 cents a pound, with a yield of sixteen pounds to a bushel of seed. There are but seven regular mills in the country. The medical profession has had a trust in castor-oil for many years, in doses of from one to four drachms.

Preventing Consumption.—The New York City Board of Health has issued the following rules to be observed for the prevention of the spread of consumption: Pulmonary tuberculosis (consumption) is directly communicated from one person to another. The germ of the disease exists in the expectoration of persons afflicted with it. The following extract from the report of the pathologists of the Health Department explains the means by which the disease may be transmitted: "Tuberculosis is commonly produced in the lungs (which are the organs most frequently affected) by breathing air in which living germs are suspended as dust. The material which is coughed up, sometimes in large quantities, by persons suffering from consumption contains these germs often in enormous numbers . . . This material when expectorated frequently lodges in places where it dries, as on the street, floors, carpets, handkerchiefs, etc. After drying in one way or another, it is very apt to become pulverized and float in the air as dust." By observing the following rules the danger of catching the disease will be reduced to a minimum: 1, Do not permit persons suspected to have consumption to spit on the floor or on cloths unless the latter be immediately burned. The spittle of persons suspected to have consumption should be caught in earthen or glass dishes containing the following solution: Corrosive sublimate, 1 part; water, 1,000 parts. 2. Do not sleep in a room occupied by a person suspected of having consumption. The living-rooms of a consumptive patient should have as little furniture as practicable. Hangings should be especially avoided. The use of carpets, rugs, etc., ought always to be avoided. 3. Do not fail to wash thoroughly the eating utensils of a person suspected of having consumption as soon after eating as possible, using boiling water for the purpose. 4. Do not mingle the unwashed clothing of consumptive patients with similar clothing of other persons. 5. Do not fail to catch the bowel-discharges of consumptive patients, with diarrhœa, in a vessel containing corrosive sublimate, 1 part; water, 1,000 parts. 6. Do not fail to consult the family physician regarding the social relations of persons suffering from suspected consumption. 7. Do not permit mothers suspected of having consumption to nurse their offspring. 8. Household pets (animals or birds) are quite susceptible to tuberculosis; therefore, do not expose them to persons afflicted with consumption; also do not keep, but destroy at once, all household pets suspected of having consumption, otherwise they may give it to human beings. 9. Do not fail to thoroughly cleanse the floors, walls, and ceilings of the living- and sleeping-rooms of persons suffering from consumption at least once in two weeks. Ten thousand copies of the report were ordered to be printed for distribution.

A Resolution has been adopted by the Board of Health, directing the Register of Vital Statistics to make a daily report of all deaths which occur in tenement-houses from tubercular meningitis and pulmonary and intestinal tuberculosis, which are to be sent to Dr. Cyrus Edson for investigation.

A Septic Suppuration has recently been produced by Dr. Kaufmann, working in Schmiedeberg's laboratory, through the subcutaneous injection of a sterilized solution of digitotoxin in absolute alcohol with ten per cent. of carbolic acid.

A Healthful Costume.—According to the *Business Woman's Journal*, the present style of the Directoire suit is probably the most hygienic dress that has ever been worn by woman. The absence of full drapery and the plain skirts prevent it from encumbering the limbs, and relieve it from the unnecessary weight which has been so serious an objection to the old styles.

The Plumber.—The *Sanitary News* is at pains to deny that there is no good plumber but a dead one; it offers arguments of considerable weight in support of its view.

## American Medical Association.

FORTIETH ANNUAL MEETING,

*Held at Newport, R. I., June 25, 26, 27, 28, 1889.*

(Continued from page 26.)

SECTION ON PRACTICE OF MEDICINE, MATERIA MEDICA, AND PHYSIOLOGY.

THIRD DAY, THURSDAY, JUNE 27TH.

DR. VICTOR C. VAUGHAN, of Ann Arbor, Mich., read a paper entitled

THE ETIOLOGY AND PATHOLOGY OF TYPHOID FEVER.

The germ is found practically in every case of typhoid fever. Indeed, it is so invariably found that one is often suspicious, for this germ of Eberth has been reported found in almost all the organs, including the brain, lungs, and the blood. It has been found, by numerous writers, in drinking-water. Pure cultures of it may be found in all our laboratories. Goffky was the first to inoculate animals with these cultures, the inoculation being made into the blood or the peritoneal cavity. Many of these died of tuberculosis. In successful inoculations, the animals died in from a few hours to four to six days. Many of the glands were enlarged, the micro-organism was found in the liver, spleen, and blood, but not at the point of inoculation. This was supposed to be true typhoid. Some found that the effect on the animal was in direct proportion to the amount injected, and other organisms produced the same result, showing that death occurred from intoxication, and that it was not specific. Thus it was shown that death was not caused by the Eberth germ.

Eberth's germ, found in the body, has been isolated and cultivated outside of the body, does not grow in the body, and soon dies. Experiments on man might produce different results. The chemical products produced by this germ must be considered also. Typhoid fever is probably due to a mixed infection, as experiments made with impure cultures help to show. Feeding on typhoid stools produces symptoms and signs much like typhoid fever. Rabbits fed with drinking-water known to cause typhoid fever, gave many symptoms of typhoid fever, and death resulted in from two to eight weeks. Vaughan found in drinking-water known to cause typhoid fever, at Iowa City, germs exactly like Eberth's germ in morphology and behavior. Dogs inoculated with this water showed, after several weeks, evident signs of typhoid fever, as shown in the autopsy. One of these dogs died, and the others became emaciated, and they showed rise of temperature. Soon after, the second dog died, and showed same signs as in the first dog. Vaughan had lately turned his attention to studying the ptomaïnes in the typhoid stools of patients. The stools were received in sterilized vessels directly from the patients, and were studied with all possible caution. He had obtained certain crystals, a solution of which, injected into the abdomen of a dog, elevated the temperature, caused purging and straining. All these symptoms give a hope that these ptomaïnes are the ones always present in typhoid. When the cultures were kept at 40° C. (104° F.) the ptomaïnes were then most abundant. It is not feasible yet to give a name to this substance.

DR. WELCH, of Baltimore, said that

HE MUST PROTEST AGAINST ACCEPTING ONE CONDITION

which Dr. Vaughan formulated, viz., that before we admit that a given micro-organism is the cause of a disease we must isolate from cultures of this organism chemical products which are capable, by inoculation or feeding, of producing the symptoms of this disease. It is certainly an important addition to our knowledge of a disease to become acquainted with such chemical products, but this is not essential to a belief in the causative agency of a specific micro-organism. If Dr. Vaughan's condition be accepted as an essential link in the chain of proof, then we have not sufficient evidence that many recognized infectious organisms, such as the spirillum of relapsing fever, the bacillus of leprosy, or even the tubercle bacillus, are the causes of their respective diseases. From our present knowledge we are justified in believing that a micro-organism which is invariably associated with a disease, which is always found in the lesions of the disease, and in situations which explain the lesions and symptoms, and which is never found except in association with the disease, must be regarded as the cause of the disease. Where, in addition to this, we are able, by experiments on animals, to reproduce the disease by inoculation or ingestion of pure cultures, this additional proof is most welcome, but in many infectious diseases we cannot furnish this last method of proof, either because we have not been able to isolate and cultivate the suspected organism, as is the case with relapsing fever, or because animals available for experiments are not susceptible to the disease, as seems to be true of typhoid fever and cholera. For this reason we may agree with Koch, that it is not absolutely necessary that we reproduce the disease experimentally in animals by inoculation before we admit that a given organism, found invariably associated with the disease under the conditions stated, is the specific cause of the disease. The evidence Dr. Welch believed to be conclusive that the typhoid bacillus is the specific cause of typhoid fever.

Dr. Vaughan's emphasis of the necessity of demonstrating the chemical products of pathogenic micro-organisms before we accept their etiological significance he perhaps bases upon the assumption that infectious organisms produce their disastrous effects solely by their chemical products; but this assumption is unwarrantable. In fact, there is reason to believe that, while some pathogenic micro-organisms act by their chemical products, others do not so act.

As Dr. Vaughan himself is doubtful as to the interpretation of his experiments on dogs, Dr. Welch was not inclined to attribute to them, without further experiments, any bearing upon the etiology of typhoid fever.

Dr. Vaughan is to be congratulated, said Dr. Welch, upon the isolation from typhoid stools of a definite crystalline substance with such interesting properties, but, as Dr. Vaughan himself has stated, it will be necessary to make control chemical observations with diarrhœal or other stools not derived from typhoid patients before the relation of this substance to typhoid fever becomes clear.

DR. JAMES TYSON, of Philadelphia, thought the organism should be found in the diseased animal, should produce the disease in a second animal, and it should be found in the second animal. This seemed to be proof enough that the organism is found irrespective of the disease and location of the lesions.

DR. T. C. WILSON, of Philadelphia, inferred from Dr. Vaughan's remarks that he was using this knowledge of the presence of ptomaïnes as a beginning simply, and was working out from this point. The clinician and the bacteriologist have not done all; there are waste places, and here the chemist, and especially the bacteriological chemist, could help us and had helped, and we should welcome the help they offered.

DR. W. J. SCOTT, of Cleveland, did not think we should expect to find the organism in the second animal poisoned by the ptomaïnes of the first. How could we expect to get bacilli from ptomaïnes?

DR. VAUGHAN, in conclusion, said that in a recent talk with Koch, the latter said he did not think the Eberth bacillus was the cause of typhoid fever, and he gave Koch's four rules, and when these rules had been complied with there could be no doubt of that disease. Dr. Welch asked us to give up every rule except the first. He did not mean to say that every disease produced its deleterious effects by its ptomaïnes, but it had been

proved in the case of many diseases; and of these diseases Asiatic cholera is the best example.

Dr. J. C. Wilson, of Philadelphia, then read a paper entitled

PROPHYLAXIS OF TUBERCULOSIS.

He began by saying that pulmonary consumption was hereditary, contagious, and preventable. So many diseases whose history is familiar to us pass from parent to child, some appearing early, some later, but all showing a clear hereditary history. Tuberculous diseases do not correspond to the acute infectious diseases whose history we know. Tuberculosis in general seems to pass not through the blood, but by local contagion from parent to offspring. We should not, and do not, speak of a tubercular diathesis any more than we speak of a typhoid or of a variolous diathesis. Tuberculosis may be caused by the flesh of animals. The careless manner in which the sputum is deposited in handkerchiefs, open cups, etc., tends to spread the disease. Animals which feed on tuberculous flesh contract the disease. Cornet found the bacilli in the scrapings of walls, etc., of rooms, hospitals, etc. He concluded that the dried bacilli were drawn into the lungs and thus caused the disease. Milk from cows with tuberculous teats may give the disease to infants Flick, of Philadelphia, showed that tuberculosis spread by neighborhood, contact, etc. The mortality is high in prisons, cloisters, etc., and the disease attacks by preference those who attend the consumptive. Monkeys, when confined in menageries, die by tuberculosis. As tuberculosis is not hereditary in the strict sense of the term, prevention is not so hopeless. The avenues of infection are by the respiratory and digestive tracts. Rigid inspection of food—animals' milk, diseased and impure —would do much good. The nature of the disease should be communicated to the patient and his friends as early as possible.

Dr. C. G. Stockton, of Buffalo, did not altogether believe in a tubercular diathesis.

Dr. Solly, of Colorado, in his practice saw all varieties of the disease, and thought it was hard to say what amount of lesion was sufficient to cause the disease.

Dr. Herrick, of Cleveland, was very sceptical on this subject. The tests of microscopy and therapeutics are wanting to support this theory.

Dr. S. Solis-Cohen, of Philadelphia, thought it was natural to be sceptical. It was almost like a repetition of ancient belief in certain old theories. It was not always certain which was first, the disease or the organism. We must draw the line between phthisis and tuberculosis.

Dr. Cutter, of New York, believed that consumption was curable, and we should not take away hope from the patient.

Dr. Whitney, of Pawtucket, thought that the germ theory had worked more harm than good.

Dr. J. C. Wilson, in conclusion, said the development of a single case proved nothing. The fact that some points still remain unsolved should not make us exclude what is known.

Dr. M. R. Crane, of Rutland, Vt., then read a paper entitled

TOXIC AGENTS IN THE BLOOD AS A CAUSE OF DISEASES OF THE NERVOUS SYSTEM,

in which was reviewed our knowledge of ptomaïnes, and leucomaïnes, and the diseases produced by these toxic agents, such as neuritis, neuralgia, diseases of the spine, cerebral disorders, tubercular meningitis, convulsions, neurasthenia, etc.

Dr. W. L. Schenck, of Kansas City, then read a paper entitled

SOME THOUGHTS ON THE ETIOLOGY, PATHOLOGY, AND THERAPEUTICS OF PHTHISIS PULMONALIS,

the substance of which was a plea for the use of fat, the absence of which in the diet seemed to increase the mortality in a people, as evidenced in the inhabitants of the warmest and coldest climates.

Dr. Solomon Solis-Cohen, of Philadelphia, read a paper on

FOOD IN THE TREATMENT OF PULMONARY CONSUMPTION.

Though the paper was in its scope therapeutic, yet as therapeusis must be founded on sound pathology, it was necessary, the author said, to state that the morbid physiology of the disease, and not its bacteriology, is considered the fundamental indication. In deference to prevailing views, tuberculosis may for the present be granted to be the history of the growth, life, and activity of a bacillus. But for rational treatment we must revert to the views of Niemeyer, who said that the danger of phthisis is tuberculosis; or to those of Rush, who declared that tubercle and other anatomical lesions were "the effect, not the cause, of pulmonary consumption;" and recognize the disease we have to combat not in epiphenomena of possible microbic origin, but in the consumption, the aberration of nutrition, which precedes the entrance of the microbe. Consumption is a disease of nutrition whose exact mechanism is as yet unknown, though the results of prolonged observation justify us in considering heredity, unhygienic surroundings, and, in general, those influences called "depressing," as among its remote or proximate causes; the pulmonary form being further dependent upon errors in respiration, whether of the substances respired or of the performance of the act.

Thus we dismiss as futile microbicidal treatment, and recognize ptomaïnes of bacillary origin only as giving rise to intercurrent symptoms which may call for antidotal or symptomatic treatment. Fixing attention upon the malnutrition, which is not a mere "predisposition" to succumb to a bacillus, but the essence of the whole morbid process, we combat it by direct measures, hygienic and medicinal, the latter secondary, the former all-important. Chief among hygienic measures is food. Food consists not alone of meat and drink, but also of air. Full respiratory diet is necessary to the utilization of alimentary diet. As in diabetes, so in phthisis, there is imperfect metabolism of carbohydrates. Experience shows a nitrogenous dietary to be best. Debove has shown that consumptives can assimilate a quantity of food far in excess of the needs of the healthy organism. This excessive quantity should be supplied; though resort to the stomach-tube, as in Debove's experiments, can be reserved for special cases.

Meat, principally beef, with milk, fish, eggs, leguminous vegetables and greens, should form the bulk of the dietary; with the addition of fat, in large quantities, in the form of cream, butter, oil-dressing for salads, or, if necessary, cod-liver oil or oleaginous inunctions. Alcohol is a food in consumption. It should be combined with malt, milk, glycerine, or cod-liver oil. Not more than three, at most four, hours, except during sleep, should be allowed to elapse without taking food. Milk punch on going to bed, and a glass of wine or spirits with liquid peptonoids in case of waking during the night, are strongly urged. Hot water before meals, lavage if necessary, to prepare the alimentary tract for the digestion and absorption of increased food, and the free drinking of water to wash out waste products, are essential to success. Predigested foods may be employed with great benefit, especially peptonized milk and beef peptonoids. In case gavage is resorted to, they should be used almost exclusively. Gavage is best preceded by lavage with an alkaline solution and chloroform water. Proper alimentary diet being secured through over-feeding, and the digestive tract and its adnexa being kept in good condition, proper respiratory diet must be supplied. Open-air life, exercise on horseback, or bicycle, voluntary respiratory gymnastics, may suffice when the patient is still strong enough. In the majority of cases, there must be some artificial aid. The inhalation of compressed air, with or without expiration into rarefied air, is the best means. Apparatus should be sim-

ple and cheap, so that the patient can use it at home. The principles laid down by Waldenburg are the correct ones. Cohen's apparatus consists of a bellows and a small gasometer modelled upon Waldenburg's. Its advantages are cheapness, simplicity, and small size, fitting it for home use. After patients are sufficiently advanced toward recovery, the pneumatic resistance valves of the author, a still more convenient and very cheap pocket-apparatus (costing about five dollars) may be used. It may be used in the first instance with strong patients. It is also useful as a prophylactic measure with ill-developed children. It gives the effects of breathing against pressure, *i.e.*, into compressed air, or out of rarefied air.

The effects of pneumatic measures are to increase the volume of respired air, open up unused air-cells, facilitate expulsion of pathological products, increase gaseous exchange, facilitate absorption of oxygen by the hæmoglobin, while at the same time the volume of blood and the activity of circulation in the lungs is increased, bringing more corpuscles into contact with the increased volume of oxygen. Penetration of blood into the tissues, tissue respiration, and production of lymph are also increased. Thus local and general nutrition are powerfully stimulated, and an improved respiratory habit and increased respiratory and circulatory power are gained. The products of digestion are properly oxidized and utilized, immature tissue is destroyed and expelled. The promotion of sleep is one of the most marked effects.

The physician thus, by altering his patients' environment in the manner described, puts them into a condition where natural powers complete the cure, and bacilli need not be feared. Illustrative cases were cited, and the conclusion reached that the proper treatment of consumption is not microbicide, but nutrition.

Dr. T. A. Cutter then read a paper entitled

TROPHOPATHY IN THE FATTY AND FIBROID DEGENERATIONS,

which dealt with the treatment of certain cases of serious kidney trouble.

## SECTION ON PRACTICE.

### Fourth Day, Friday, June 28th.

Dr. J. G. Truax, of New York, read a paper on

ULCERATIVE ENDOCARDITIS,

in which he reported six cases, drawing attention to certain points. The symptoms were not pathognomonic, the heart-sounds were often found normal on auscultation, the temperature never rose above 104° F.; the infection is undoubtedly due to some germ.

Dr. Mary E. Baldwin, of Newport, read a paper entitled

STOMACH REST AND CLEANLINESS,

in which was related a case treated by proper diet, stomach washing, stomach rest by enemata, change of scene and air, and the results were successful. The constipation which was so obstinate has been entirely removed, and the bowels were regular. The abuse of the stomach during infancy and childhood is undoubtedly an important causative factor in such cases.

Dr. W. S. Watson, of Matteawan, N. Y., then read a paper on

ADDISON'S DISEASE,

with exhibition of a specimen. After enumerating the symptoms and history of the ordinary type of this disease, the writer spoke of the experiments made in incision of the supra-renal capsules. These glands contain a large number of vessels and nerves, indeed, larger in proportion to their size than any other gland in the body. In a case terminating fatally he had found at the autopsy heart, lungs, normal; the supra-capsules normal in size, but much changed and inflamed on microscopic examination. In reply to the Chairman, Dr. F. B. Shattuck, Dr. Watson said there was no increased pigment on the mucous membrane of the mouth.

## SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

### Third Day, Thursday, June 27th.

Dr. William H. Taylor, of Cincinnati, related a case in which

PREGNANCY OCCURRED AS A COMPLICATION OF OVARIAN TUMOR.

He was called to see a woman who expected to be delivered in January. She was not delivered in that month. In February she met with an accident, being thrown from her carriage, and he was allowed an examination. He told her that she was not pregnant, but that she had a tumor, and recommended treatment for it. She insisted she was pregnant, and would permit no treatment. Eighteen months after he was first called to deliver her she passed a blighted ovum. He was criticised very much by the patient and her friends, but he told them that he laughs best who laughs last, for he had re-examined her and found the tumor still distinctly present. The woman went on growing, and, being very short in stature, she became greater in circumference than height. She finally died. The doctor was sure that the pregnancy occurred after he was called to attend her.

Dr. A. Van Der Veer, of Albany, N. Y., was of the opinion that the complication of ovarian tumor with pregnancy would grow less and less common as our ability to diagnose improved, but with fibroid tumors it would not be so. Nothing so lowers us in the confidence of our patients and their friends as the operating on a pregnant uterus. He called attention to the fact that Peaslee had a case of tetanus after ovariotomy which he thought due to the use of a clamp, and he always argued against the use of a clamp thereafter.

Dr. Kimbel, of Lowell, Mass., reported four cases of tetanus following ovariotomy which occurred in his practice. His experience with tetanus following ovariotomy had been extremely unfortunate. A peculiarity of his case was that the tetanus had not come on till the twelfth day in one case. The patient grew worse and died. He has had three cases since, two of which died. The fourth case recovered. He did not know that any treatment had any particular power over this disease, but thought more reliance could be placed on opium than anything else.

Dr. Kirby, of Pennsylvania, had removed an ovarian tumor weighing thirty seven pounds from a woman who was pregnant, and the pregnancy went on to term and a healthy child was born.

Dr. Theophilus Parvin, of Philadelphia, read a paper entitled

CASUISTRY IN OBSTETRICS.

Zoroaster, long before Cicero, gave us the maxim which contained the teachings of Cicero, "In doubt as to whether an action is right or is wrong, abstain." The order of Jesuits has given especial attention to this subject. Zoroaster's rule is excellent, but will not always do in obstetrics, because we cannot in all cases abstain; we must do something. Casuistry sometimes perverts, as in the case of the wife who excused her adultery by saying that she gave her body to her lover, but not her lips, with which she had made her vows of fidelity.

THE TREATMENT OF ECTOPIC PREGNANCY

in its earlier stages is one of the pressing questions of the hour. The progress of science brings up new questions in casuistry in obstetrics. The ophthalmologist finds albuminuric retinitis in the pregnant woman, and tells her physician that the continuation of her pregnancy is at the peril of her vision, and possibly of her life. The speaker thought that woman when pregnant should be treated as

well as other animals in a similar condition. Continence for months or years is possible, and not injurious. Notwithstanding the many influences brought to bear on the physician to prevent conception, he takes great responsibility who attempts to thwart nature's law. Information of this sort, if given even to those who may seem to require it, will soon become general, and a strong defence to female virtue will be taken away.

CRANIOTOMY

he considered one of the most painful, serious, and difficult questions in casuistry in obstetrics. He reported several cases in which the operation had been performed, and the child had to be killed after delivery, or partial delivery. Those who advise craniotomy on the living fœtus cannot decide on the measurements of the conjugate which demand it. The field of craniotomy is being steadily restricted, but that it will entirely disappear, except for hydrocephalus, few are sanguine enough to believe. Amputation of the pregnant uterus is destined to occupy a more prominent position than it has yet done. It is yet to be decided whether hysterectomy or hysterotomy will save the larger number of patients.

Dr. Wm. H. Parrish, of Philadelphia, then read a paper on

PELVIC ABSCESS IN THE FEMALE.

He divided this into three subdivisions, areolar, intratubal, and ovarian. Chronic pelvic cellulitis occurs only as a sequel to pelvic abscess. We usually have the history of gonorrhœa in the husband, dyspareunia in the woman. He had never met with an areolar abscess dependent upon extension of gonorrhœal inflammation from the vagina or uterus directly through the walls of these organs into the pelvic areolar tissue. Chronic cellulitis, unless becoming such by complication, is a gynecological myth, and has an existence only as an ignis fatuus in the brains of former members of the profession. Abdominal surgery has demonstrated in numerous instances that chronic cellulitis has no independent existence. That intra-tubal abscess occurs with very much greater frequency than areolar abscess must appear to every one familiar with abdominal surgery. The successful treatment of pelvic abscess often demands an exercise of the most deliberate judgment and the highest operative skill. The speaker urged the necessity of operating early in every variety of curable pelvic abscess. The besetting sin of the family practitioner and the timid and doubting operator is to wait. In this delay the dangers become cumulative and the surgeon is asked to operate when the case has become hopeless. If the patient dies the practitioner is discouraged, and in his next case he waits longer still in the hope that pus may not form, or that it may escape spontaneously. He thinks that in some of his cases suppuration has taken place, resolution followed, and so justifies his delay. Early surgical interference with the knife should be the rule in all varieties of pelvic cellulitis.

Dr. A. Reeves Jackson, of Chicago, read a paper on

INJURIES OF THE BLADDER DURING LAPAROTOMY.

Details more or less complete were given of sixty-seven cases which had been collected by the author from various sources. Some of them had been already published, but the greater number were obtained through personal correspondence with the operators in whose practice the accidents happened, and were made known for the first time.

Considering the conditions under which bladder injuries may happen during laparotomy, it is not necessarily discreditable to any surgeon to meet with them, for they may not be due to any carelessness or lack of skill on his part. In many of the cases cited no possible degree of diligence could have averted the accident. Adhesions of the peritoneal surface of the elongated bladder to that of the anterior abdominal wall frequently cannot be known in advance, and their existence is only demonstrable after the viscus has been opened. The use of the catheter as a diagnostic means is not always available, because the compression of the bladder against the pubis may prevent the introduction of the instrument beyond that point. Certainly, however, this attempt should always be made in any case of suspected difficulty, and would seem to be even a proper and unobjectionable routine method. Another useful precaution is to avoid prolonging the abdominal incision far down toward the pubic bone, until the opening into the peritoneum has permitted the relations of the bladder to be ascertained.

The mortality of the cases in which the bladder has been wounded is large, namely, about thirty per cent., but this is due to the complicated and serious character of the cases in which the accident has occurred, the consequently increased length of the operation, and the greater danger from shock, rather than to the mere vesical injury. The latter, indeed, does not seem of itself to be very important as influencing the recovery of the patient. But, notwithstanding this fact, a urinary fistula adds greatly to her discomfort, and, occurring under such circumstances, must be productive of chagrin and annoyance to the surgeon.

Inasmuch as the bladder is recognizable with more difficulty when empty than when full, it would be better, in cases presenting doubtful features, to commence the operation with the viscus wholly or partly distended. When its position has become known, after the completion of the abdominal incision it may be emptied by an assistant.

TREATMENT OF INJURIES OF THE BLADDER DURING LAPAROTOMY.

When it is known at the time of operation that the bladder has been cut or torn, the opening should be at once closed with a continuous suture of catgut or fine silk, applied so as to invert the edges of the wound and bring together the serous surfaces. A permanent catheter ought to be used during the first two days. After the expiration of that time, its constant use is usually unnecessary; and, if the wound is small—less than an inch in length—the instrument may be subsequently dispensed with. If, however, the wound is large—exceeding two or three inches—the bladder ought to be artificially emptied during three or four days additional. In all cases the catheter should be used so long as the urine contains blood.

In the cases in which urine appears through the abdominal wound subsequently to the operation, at a time and under circumstances which may make it dangerous or inexpedient to reach the seat of the vesical injury, the catheter ought to be used either continuously, or at short intervals, for the purpose of lessening the amount of urine which escapes through the fistula, and thus aiding in the closure of the latter. If, however, the fistulous opening shows no disposition to close after two or three months, the edges should be freshened to the depth of half an inch or more, and stitched together.

In exceptional instances it may be expedient to affix the wounded edges of the bladder within those of the abdominal incision, in the manner detailed by Thomas and others; but as this plan must interfere to some extent with the subsequent contractility of the bladder, it is not to be commended as a usual practice. The suturing and "dropping" of the vesical wound is the better method.

Dr. A. B. Carpenter, of Cleveland, read a paper entitled

ALEXANDER'S OPERATION, WITH A NEW METHOD FOR SECURING THE ROUND LIGAMENTS.

The speaker confined himself principally to a few remarks regarding the fastening of the round ligaments. As a radical cure for this most distressing condition he believed the Alexander operation had no equal, because of the simplicity of the work and the comparative, indeed almost absolute, freedom from mortality. Deaths have been recorded as resulting directly from the operation,

yet this occurred in the early time before the detail was well understood.

The greatest objection raised in the past against this method has been the difficulty in finding the round ligaments. This, however, applied chiefly to the operations for retroversion and retroflection where the ligaments were small and very fragile, breaking while being drawn out, and causing the operation to be abandoned as incomplete, and the surgeon to bear the blame of his work being a failure. . . .

In cases of complete prolapsus it is entirely different, the ligaments have become thickened and greatly enlarged, the difficulty in finding them in most cases is entirely removed; the many years of constant dragging upon the ligaments usually resulting in an hypertrophied condition, so that, instead of being small and fragile, we find them of much greater proportions; so that, by first replacing the uterus and then having it held well up by a sound in its cavity, the ligaments can be carefully drawn out with little or no danger of their breaking.

In 1885, the speaker had the pleasure of listening to a paper by Dr. Alexander himself, read before the British Gynecological Society, wherein the method of shortening the round ligaments was described, and he was particularly impressed with what seemed to him to be the insecurity of the fastenings.

If we consider, he said, the structures involved, the dense unyielding fibres of the pillars of the external ab dominal ring, at the same time the round, smooth character of the ligaments, composed as they are of dense fibrous tissues, thus affording a limited opportunity for the formation of strong adhesions in the wound, it seemed to him that a reasonable explanation could be found why many of the cases that have been operated upon have reported themselves in after months as not improved, the anchorage being so slight and frail that the uterus, by continually dragging, tears the ligaments loose and gradually settles down to its old position.

The author's method is the following: The uterus being replaced and held high up by an assistant, the incisions are made and ligaments on either side drawn out until the uterus is found to be well up and forward, a needle armed with a silver wire No. 26 is then passed through the external pillar of the ring, through the round ligament, then through the internal ring; this is then twisted down firmly, cut off, and the ends bent over and crushed down, that they may cause no irritation. The slack of the ligaments is then cut off, leaving just sufficient to fill the bottom of the wound. The ligaments are then split to within a short distance of the silver wire and turned partly outward from each other, and stitched with fine gut to the lateral walls of the wound, the latter being then closed, a small drainage-tube inserted, and the whole covered by an antiseptic dressing. The silver wire is left to become permanently encysted, and thus hold the ligaments firmly in place.

A high posterior plastic operation should then be made on the vagina, and upon the removal of the sutures from the latter operation, a Hodge, or perhaps what is better, an Albert Smith pessary with a high bar, should be introduced and worn for not less than six months.

This method of fastening the round ligaments was, in the author's opinion, superior to any with which he was acquainted, as it afforded a firm anchorage and prevented the uterus from dragging upon the ligaments, thus drawing them gradually out, and defeating entirely the object of the operation.

Dr. A. Cordes, of Geneva, Switzerland, exhibited

A NEW TWO-WAYS CATHETER FOR UTERINE INJECTION.

He had a new catheter made in Paris, consisting of one tube sliding into another so as to permit of thorough cleansing and scrubbing in every corner where microbes might penetrate. This did not act well, for it could not be made watertight without making it too hard to work. In his new catheter he uses Bozeman's form of the sigmoid flexure. He hoped to have it made of hard rubber, which does not corrode in bichloride or any other liquid. He then described and criticised the instruments of Doléris, and Pajot, Roderier, and Olivier. Cordes' instrument has no rigid tube, no screw, no blind end, or cul-de-sac, no angle, no corners where the microbe could hide, and no eyelets. Being open on the distal end it throws the fluid into the fundus uteri, from whence it comes down and returns by the exit channel. The idea of two grooves came to him on looking at the horse-shoe catheter of Budin.

Dr. Augustus P. Clark, of Cambridge, Mass., read a paper on

CHRONIC CYSTITIS IN THE FEMALE.

Few diseases prove to gynecologists so vexatious or intractable as chronic cystitis. The lesion, or morbid causes giving rise to cystitis are numerous, whether it be the acute or chronic form. Each case merits separate consideration. The arrangement of the muscular coat of the bladder is such as to give it a wonderful immunity against ordinary accidents and conditions which occur in the viscus itself. This fact should make us remember that symptoms present in a case of cystitis are often but an expression of the organ that there has occurred a lesion or a morbid process at a distance from the part seemingly affected. Anal and rectal inflammation are not uncommon causes of cystitis. Resort to dilatation of the urethra will be followed by the best results in cases where tenesmus is an important symptom, and in which the parts around have been contracted and hypertrophied. Faradism with one pole near the uterus and the other over the bladder gives speedy relief. Corrosive sublimate, 1 to 2,000, will often prove of benefit when no marked organic changes have occurred, the train of symptoms due to suppuration, fermentation, and the uncleanliness generally. No general rule of application can be laid down in all cases. Some will yield readily, others will defy all recognized methods of treatment, and can be cured or corrected only after the most ingenious and skilful operation.

Dr. A. S. Gordon, of Portland, Me., reported

A SUCCESSFUL OPERATION FOR EXTRA-UTERINE PREGNANCY.

He had on a former occasion reported to this Section his first case, which he supposed to be the second successful case in America, but which he now knew to be the third. The case ran as follows: February, 1888, Mrs. B—— missed her menses. She was twenty five years of age, married eight years, and had never been pregnant nor used means to prevent pregnancy. March, April, and May were missed. June 1st, she was taken with a severe agonizing pain in the abdomen, but finally got relief. Operation was made and a fœtus at three and a half months was taken out. He believed that just as soon as a diagnosis of extra uterine pregnancy was made, we should open the abdomen and remove the fœtus.

THE USE OF GALVANISM IS SIMPLY MALPRACTICE,

he said. If we can make a diagnosis, and he thought as a rule we could, we should operate. He did not believe that we could make a diagnosis in ninety-five per cent. of the cases, as had been claimed, but we could in a great many.

The paper was discussed by Drs. Taylor, of Cincinnati; Currier, of New York; Cushing, of Boston; Hoffman, Price, and Baldy, of Philadelphia. The strong statements of Dr. Gordon concerning electricity were considerably modified by the discussion.

Several other papers were read by title, and the session then adjourned.

---

A Colorado Physician recently held the body of a Kansas man, who died, for the payment of his bill, amounting to $3,600. Report does not state whether it was effectual in securing the money.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, June* 6, 1889.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

DR. PRINCE A. MORROW related

PERSONAL OBSERVATIONS OF LEPROSY IN MEXICO AND THE SANDWICH ISLANDS,

and gave magic-lantern illustrations of typical cases. Leprosy, he said, possessed only a historical interest to the majority of persons; it was by them classed in the same category as pestilences and plagues, which formerly devastated countries but which now were extinct. Unfortunately, however, it was not to be so regarded; it was a living, an actual reality. In area it embraced fully one-third the surface of the globe. By reference to a map which he exhibited, it would be seen to extend from the tropics to the Arctic regions; it embraced every variety of soil and climate; it affected most diverse peoples.

Thus climate, soil, and race could not be regarded, as had been done by some, as efficient factors in etiology. It would be impossible to estimate the exact number of lepers on the face of the earth, but India alone was supposed to have fully one hundred and fifty thousand, China and Japan contained large numbers, and there were many in Egypt and other portions of Africa, South America, and elsewhere. There were from five to ten thousand in Brazil.

Whenever leprosy appeared in a country in which it had not been known before, it could be traced to a human agent. It never originated spontaneously. There was good authority for the assertion that the disease was introduced into Central America by the Portuguese, into Mexico by the Spaniards, and into Canada by the French. In the United States it could be traced to at least three or four distinct sources, according to the locality. In California it was introduced by the Chinese, in the Northwest by the Scandinavians, etc. He called attention to the fact that a centre not yet mentioned was Salt Lake City, where it had been brought by Mormon converts from the Sandwich Islands.

His own observations began the past winter about New Orleans. It had become well known that Dr. Blanc had alone seen forty-two cases in that city. He had learned during his visit that cases were scattered here and there at different places about New Orleans. He saw a number in Mexico, and in San Francisco he found six or eight in the pest-house, three of them being Chinese and one a negro. The Sandwich Islands afforded perhaps the best opportunity for studying the disease of any place in the world. There were many cases on the Islands, and they were segregated. In other countries certain elements of confusion surrounded the origin and general study of the disease which were absent here. It was easier to arrive at the truth with regard to the influence of heredity, race, etc., in the Sandwich Islands, where the disease had been introduced within half a century. There were nearly eleven hundred cases in the settlement at Molokai when Dr. Morrow was there.

Most of our positive knowledge of leprosy has been developed by modern methods, and might be formulated as follows: It was a parasitic disease; the leper bacillus presented certain analogies with the bacillus of tuberculosis. Like the latter, it was endowed with remarkable vital tenacity, and, like all specific microbes, it showed an affinity for certain tissues rather than for others. It was found in the nodular infiltrations upon the skin and mucous membranes; it was abundant in the lymphatic spaces; it was present in the liver, spleen, testicles; very abundant in the connective tissue and peripheral nerves; it was absent from the blood, from the urine, and, as far as known, from the physiological secretions. It was present in abundance in the vaccine pustule of leprous patients. It never originated spontaneously; it did not attach to the soil, water, air, or food; it could always be traced to man. It was known, further, that leprosy had a somewhat prolonged, although undetermined, period of incubation, varying perhaps from three to five years, but in some cases it seemed to have been prolonged to seven, ten, or even fifteen years. The prodromal symptoms were often very indefinite; when well developed, however, the disease had a characteristic symptomatology. It was slow and irregular in course, and progressed almost invariably to a fatal issue.

Belief in the contagiousness of leprosy had been almost universal until recent times. After the Royal College of Physicians of London formulated the dogma, in 1867, that leprosy was not contagious, this view gained very considerable ground. In the United States, however, the leading dermatologists had never accepted the heresy of non-contagion. The history of its development and course in the Sandwich Islands afforded most conclusive evidence of its being contagious. Upon no other possible ground could its diffusion among the native population be explained. At the present time it was supposed from five to ten per cent. of the Sandwich Islanders were lepers. He had had opportunity to examine a great many of the patients there, and his experience had been like that of others, that in almost every instance a history of exposure could be obtained, either in sexual relations or conditions of prolonged intimate contact. One way in which the spread of the disease could be accounted for was the fact that relatives were permitted to care for the diseased in leper settlements. A large proportion of such helpers also became diseased, the percentage amounting in 1880, according to the report of the President of the Board of Health, to about one-third (twenty-three out of sixty-six helpers had contracted the disease, and eleven others were suspected). Many of the lepers came from countries where leprosy was not known, and where the question of heredity could not be entertained.

With regard to the mode of infection, our knowledge was imperfect. The probabilities were that in the large majority of cases infection took place through sexual intercourse. But it was also probable the disease could be inoculated through abrasions upon the skin and mucous membrane, and by the bite of insects. Another mode of infection was through impure vaccine, and in this manner it seemed probable a number of cases arose in the Sandwich Islands. One patient who came under Dr. Morrow's observation claimed to have acquired the disease through the bite of a leper, and another through sticking himself with a pin, which he did in a spirit of bravado, in imitation of this act by a leper who had used the same pin.

Dr. Morrow mentioned the case of the criminal who was permitted to choose between the death penalty and inoculation with the virus of leprosy and imprisonment for life. He chose the latter, was inoculated in 1884, and for some time his case was regarded as negative; but recently he had shown what Dr. Morrow regarded as unmistakable symptoms of leprosy, including the presence of the bacillus in his tissues at the point of inoculation. This was the first instance on record in which intentional inoculation had succeeded.

Belief in the heredity of leprosy has been almost universal, yet from his own observations he had found little evidence to support it. He thought, however, that a predisposition to the disease might be transmitted to offspring, as was true of tuberculosis; but he did not believe the actual germs of the disease were ever transmitted. Children never showed evidence of leprosy before the third or fourth year, usually not before the fourteenth year, while the great majority of cases occurred between the thirtieth and fiftieth years of age. Thus it would be seen that there was a certain analogy between this disease and late hereditary syphilis. Only a small proportion of the children in the Sandwich Islands, born of leprous parents developed the disease, unless exposed to prolonged contact with those thus affected.

The speaker said he was well aware that there were cases which seemed to show that leprosy was a non-contagious disease. For instance, he threw on the screen the

picture of a man who had cohabited with a leprous wife many years, and who had one daughter, aged twenty-five, who was a leper, yet he had himself remained in excellent health. There was a woman on the Islands who had had three husbands, each one of whom had become lepers, yet she remained apparently free from the disease. Was it not possible that she had had the disease without external manifestations, and had given it to her three husbands successively? It would appear that in leprosy, as in other contagious diseases, the system had to be in a receptive condition before it could be acquired on exposure. In some instances persons had remained free from the disease during an exposure of twelve or fifteen years, then contracted it and died. The author then read from his published description of the symptomatology, and showed, in the course of his illustrations, typical examples of the anæsthetic, tubercular, and mixed forms, and closed his remarks by asking the question whether there was danger of the spread of leprosy in the United States; or did the disease, under our hygienic and civilized conditions, lose its potentiality for mischief?

Dr. C. W. Allen opened the discussion on the subject of

THE DANGER OF THE SPREAD OF LEPROSY IN THE UNITED STATES.

His convictions on the subject, he said, were very decided. Two years ago, before the County Medical Society, he had expressed the view that lepers should not be admitted to this country, and that those already here should be segregated. At that time he had estimated the number of cases here at one hundred and fifty, which was considered by some to be an overestimate. He now believed, however, that there were many more. When we further considered the large numbers at Key West, Cuba, and elsewhere, likely to gain access to our mainland at any time, we could not shut our eyes to the danger. With regard to the influence of civilization being against the spread of the disease, it should be remembered that there were many cases in England only a century ago, when the conditions were essentially what they were now in this country. There were so many there then that a leper-house had to be established for their reception. With regard to evidence of the disease not being contagious, it was altogether negative, and a single fact of a positive nature was sufficient to overturn it.

Dr. L. D. Bulkley regarded the question as one of the most important ever brought before the Academy. He thought no one who had listened to the remarks of Dr. Morrow, and read the literature of the subject, could fail to be convinced that wherever leprosy had been introduced and allowed full freedom it had spread; and no one could deny that where those affected were properly cared for and segregated that the disease had disappeared. Dr. Morrow having asked the question whether the leprosy was in danger of spreading throughout this country, he would say that until the past six or eight months his fears had not been greatly excited, but he had been somewhat surprised to learn of the number of cases recently recorded in New Orleans and elsewhere, and he thought it well that the question should be agitated, that boards of health in different places should learn the number of patients in their vicinity and report them. While leprosy seemed to be conveyed by contact from one person to another, yet he saw no reason why the bacillus should not be capable of living in the water or soil.

Dr. G. H. Fox took a more hopeful view of the subject than that expressed by the other members. The cases of leprosy in this country, he said, were nearly all imported ones. They were few, in spite of the fact that there was no law prohibiting their immigration, and none compelling their segregation. Only one patient, as far as he was informed, had been cured. He was willing to grant that the disease was contagious under certain circumstances, but that there was much danger he did not believe. There was no more danger than that dogs would go mad and spread hydrophobia in a neighborhood; yet in this case the people generally did not hesitate to take the risk and keep dogs, even though they were useless. In fact, he thought that the danger of the spread of leprosy in the United States had no rational basis. He had not yet learned of its spreading throughout a civilized community. It might be different among the Sandwich Islanders, who lived in large numbers under the same roof, ate with their fingers out of the same dish, etc.; but the white people, even on the Sandwich Islands, were remarkably free from leprosy.

He thought, however, that lepers should be kept out of this country by a strict enforcement of the quarantine laws, not because of danger of spread of the disease, but because, like paupers, they were likely to become a burden to the community.

Dr. H. G. Piffard said the questions raised to-night were the same as he had asked ten years before, and the ground taken by the majority of speakers was the same as that which he had then taken. At that time the Academy appointed a committee to investigate the existence of leprosy in the United States, and it was able to learn of only forty or fifty. It was probable there were more then, but he believed there were now five times as many as ten years ago.

He advocated a strict enforcement of quarantine against all incoming lepers by the general Government, the establishment of a hospital by the same power for the reception of those who would voluntarily enter it, and forced segregation by State authority against others if thought desirable.

Dr. F. R. Sturgis thought the question of legislative interference depended altogether upon that of the contagiousness of leprosy. He did not doubt this, although there were some links lacking in the chain of proof. He thought the earlier stage was more contagious than the later. It could be admitted that there were bacilli in both syphilis and leprosy, but it was still a question whether they were the true cause of either disease. As to less danger of spread of the disease in this country than in the Sandwich Islands because our people were more cleanly, he would only suggest to Dr. Fox to go into some of the tenement-houses of New York and observe there the degree of cleanliness existing among a large part of our population; he thought it was proper for this Society to call attention of the authorities to the fact that leprosy was contagious, and that quarantine should be enforced against leprous immigrants.

Dr. R. W. Taylor said the speaker of the evening had clearly shown the possible danger of leprosy becoming endemic in this country, yet during the past fifteen years he had seen almost constantly one to three lepers sleeping in the crowded wards of the hospitals on Blackwell's Island, and in no instance had the disease been conveyed to others. While it was desirable to call attention to the existence of cases in the country, yet he believed there was no immediate danger of an endemic.

Dr. Morrow, in closing the discussion, called attention to the improved condition of the people of the Sandwich Islands over that of some twenty years ago, and said the spread of leprosy there could not be attributed to dirty habits. They washed themselves very often, perhaps half a dozen times a day. He thought the tendency of the disease to spread more rapidly in some communities in which it had gained a foothold, than in others, might be accounted for by the fact, as he believed, that the anæsthetic form was not contagious, and it was this form which predominated in some places, while the tubercular form was in the ascendency in others. He doubted also whether leprosy was contagious during the later stage. In reply to Dr. Fox, he said all would probably be in favor of enforcing strict segregation and quarantine against such contagious diseases as syphilis, tuberculosis, etc., if there were altogether but a few hundred cases, and by doing so the disease could be entirely extin-

guished. That, he believed, was what could be done in the case of leprosy.

NATIONAL BOARD OF YELLOW-FEVER EXPERTS, ETC.

The committee appointed to report on this question, consisting of Drs. Hadden, Jacobi, and Armstrong, reported that the proposed resolutions were in conflict with the Constitution of the United States, and that the present quarantine laws, if enforced, were sufficient.

DR. JOHN C. PETERS called attention to the report of the State Board of Health on the nuisances existing in the region of the Croton water-shed, and, on motion, a committee, consisting of Drs. Jacobi, Peters, and Baruch, was appointed to petition the Mayor and Aqueduct Commissioners to have the nuisances abated.

THE PRESIDENT announced that at the next meeting the architect would report on the plan of the proposed new building, after which a collation would be served, and he invited as many as could possibly do so to be present.

---

*Stated Meeting, June* 20, 1889.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

NUISANCES ON THE CROTON WATER-SHED.

The committee appointed at the last meeting, consisting of Drs. J. C. Peters, A. Jacobi, and S. Baruch, reported through its chairman, Dr. Peters, that it had thus far traced the sole responsibility of abating the nuisances to the Commissioner of Public Works, Mr. Gilroy.

On motion, the report of progress was accepted, and the committee continued.

DR. A. JACOBI then read

NOTES ON THE BAKING OF BACILLI,

being a denunciation of Weigert's advertising scheme, and a review of his own experience with the inhalation of hot air in the treatment of phthisis. Weigert, supposed to be an American physician, now of Germany, claimed to have discovered a method of curing phthisis by the inhalation of hot air, and he had made free use of Dr. Jacobi's name in advertising his apparatus for carrying out this treatment. The treatment was not original with Weigert, nor had Dr. Jacobi, as had been asserted, bought, endorsed, or recommended the apparatus in question. Moreover, as appeared further along, he had little confidence in the method. To Halter belonged the honor of suggesting the treatment of phthisis by the inhalation of hot air with the view of killing the bacilli in the lungs. The idea arose from observing the immunity from phthisis of workmen in a lime-kiln where they were exposed to a high degree of heat, 122° to 158° F., so high that it would destroy the tubercle bacilli provided it continued at that degree until it had reached the lungs. The air inhaled by workmen in a lime-kiln was dry and rarefied. A moist atmosphere of a like temperature would be more destructive of the bacilli, but was less endurable by the phthisical patient. Dr. Jacobi said, that having been requested to admit Weigert's apparatus into his wards at Bellevue Hospital, he did experiment with it some time ago, and for a while the results made a favorable impression on the physicians in attendance, for the patients, or a part of them, seemed to improve under the treatment. More careful observation, however, showed that the improvement was doubtless due to rest in the hospital, in an atmosphere much purer than that in which the patients had lived in their tenement homes. The instrument itself was not as good as that which one of ordinary ingenuity could improvise; the atmosphere on its way to the lungs from the flame was found to have fallen from above 300° F. to about the temperature of the body when it had reached the mouth. Of course if it were above the temperature of the blood it would become further cooled on its passage toward the lungs. Some of the hot air might get into the alveoli, but very little. In order to obtain benefit from such treatment it would be necessary not only that the air inhaled be of a high temperature, but that the patient be in a room in which the thermometer registered at least 105.5° F. In other words, it would be necessary to produce a sort of artificial fever, and it was evident that such treatment must prove injurious to any other than patients in the very first stage of phthisis. He added that two of his patients suffered from cough and vomiting during the treatment with hot air, and were distinctly better when it was discontinued.

MR. R. H. ROBERTSON, architect, then presented

PLANS FOR THE NEW ACADEMY BUILDING,

about to be erected in Forty-third Street, west of Fifth Avenue. The building will present a front of seventy-five feet, a depth of one hundred feet, will be four stories and a basement, be constructed of a dark-red sandstone and rock-faced brick. The first floor will be two-step rise from the sidewalk, be divided into coat, reception, smoke, and dining-rooms, and the large hall. The latter can be still further enlarged by raising the door which will separate it from the dining-room. Beginning on the next floor, three elevations will be devoted to the reference library, three reading-rooms, and one stack library with a capacity for 230,000 volumes. On the third floor will be four large section-rooms, also specimen and apparatus room. There will be a room for photography on the fourth floor, also for the librarian, and for articles which pertain to banquets. The basement will be divided into boiler, unpacking, storage, closet, and janitor's rooms.

DR. WALTER MENDELSON read some resolutions, with a preamble, practically consisting in a remonstrance against the appointment of persons to the position of President of the Board of Health who are ignorant of sanitary matters. His motion to refer the matter to the council was carried.

---

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, May* 27, 1889.

ALEXANDER S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

DR. ABRAHAM JACOBI read a paper entitled

RHEUMATISM IN INFANCY AND CHILDHOOD,

in the first part of which he mentioned the limited bibliography. It began with inaugural theses by two pupils of Roger, 1864 and 1866, followed by a paper by Roger himself in 1867. In 1875 Dr. Jacobi wrote on the subject in the first volume of E. C. Seguin's "American Clinical Lectures." Its study had been renewed to a certain extent the past five years. It was Dr. Jacobi's object to consider principally the therapeutics of acute rheumatism.

Acute rheumatism, he said, was a frequent disease of both infancy and childhood, but only few recognized it to be so. The number of cases of valvular disease of the heart, mainly of the right side, in children under five years of age ought to be suggestive to doubters of the frequency of rheumatism before that period. Nor was the number of rheumatic cases limited to those having cardiac disease; there were many cases which ran their full course without terminating in disease of the heart. The heart should be watched in every doubtful subject, for endocarditis was sometimes the first sign of the acute rheumatism of children, even in apparently mild cases. Pericarditis was not very rare. When chorea minor showed itself, the heart and the joints should be examined, for there were instances in which this disease occurred not at the end, but at the beginning, of acute rheumatism.

In adding a few words on diagnosis, he said fever was a common symptom in small children, every physical disturbance raising their temperature. In acute rheumatism it was often but slightly elevated. Sometimes it rose at irregular intervals, in some instances being highest about noon. The swelling of the joint was apt to be very trifling, and to be overlooked. Pain, either spontaneous or on pressure, was often much less than was seen after fatigue,

syphilitic disease, etc. The diagnosis was apt to be made more difficult by the affection limiting itself to but one joint temporarily, or throughout the attack. Then the disease often occurred in the knee or hip, joints much subject to traumatic and tubercular troubles. The diagnosis also failed to be made in many cases because of its being denominated growing pains, a term which should have been dropped long since. What had been called growing pains was of various origin and nature. It might be a neurosis of the joint, an epiphysitis, but in a large majority of cases it was rheumatism.

The treatment of acute articular rheumatism had been quite unsatisfactory down to modern times. A few indications were furnished by the actual or alleged causes of the disease. By some it had been regarded as endemic. It was sure that certain localities had been known to harbor a great many cases at the same time. Thus, change of home, if practicable, ought to be made, provided the case was one of a number in the same neighborhood. Contagion had been supposed to spread the malady, but the number of observations of the kind had been very limited indeed.

Rheumatism was apt to make its appearance after some infectious disease, as diphtheria, scarlet fever, dysentery, and erysipelas. Hence care devoted to those sick with these diseases would prove a powerful preventive of rheumatic fever.

The blood had been found changed, the alkalinity being less pronounced; but this change, or the actual presence of acid in the blood, had also been either proved or assumed to exist in cachectic conditions of numerous kinds. In them, as in acute rheumatism, lactic acid had been found in undue proportion, yet when introduced into the circulation it never produced articular rheumatism. The diminution of the alkalies in the blood justified the administration of an alkaline salt throughout the course of rheumatism, particularly of potassium.

Sudden changes of temperature were certainly among the causes; exposure to wind and moisture would bring on an attack. This was particularly so in those with an inherited predisposition. Such inheritance was not at all infrequent. The treatment of such cases must be mainly preventive. The tendency to be easily influenced by sudden changes of temperature could be modified or removed by the use of cold water. Warm clothing and bedding were indicated. Nothing could be more injurious than exposure of the surface to wind and rain. The swollen and painful joints must be protected against pressure of blankets. The ice-bag or cold wet cloth to the affected joint was sometimes of benefit. The wet bandage or pack, applied around the joint should be changed every hour or half-hour. Anæmic children preferred hot applications, perhaps dry ones. To relieve pain he could not advise subcutaneous injections of carbolic acid, as had been done by some. In very severe cases he had been compelled to administer a few drops of a solution of morphine hypodermically. As a rule, an anodyne application around the joint (such as chloroform, morphine), covered by oiled silk, or the use of a mild galvanic current, would give relief.

Distention of the synovial membrane during retarded convalescence was troublesome, and might be treated by compression with bandages or collodion applications, by gentle massage and the galvanic current. Iodine was useful, also the internal administration of iodide of potassium or sodium, or both, five to twenty grains daily. Officinal ointment acted through the gentle kneading necessitated by its use, but absorption did not take place. Iodide of potassium in glycerine would act better, but was inferior to lanolin ointment. Dissolve iodide of potassium in equal parts of water, and some fat and a larger quantity of lanolin, and apply to the joint. Best of all was to brush copiously iodoform collodion over the affected joint, and allow to dry. Very old cases, with chronic effusion into the joint, required aspirating and washing out.

Endocarditis demanded absolute rest, every exertion proving injurious. Hence, occasional doses of opium or bromides would have a good effect. The ice-bag, or, if too heavy, the ice-cloth to the cardiac region would act well. But not every murmur meant endocarditis. Both chorea and endocarditis could be mitigated or prevented by early attention.

The temperature was rarely high, but there were cases in which it went up to 104° or 107° F., and it was in them that delirium and other nervous symptoms made their appearance. Antipyretics were then required. The cold pack was the readiest and most effective. It was particularly indicated in cases complicated with endocarditis. It was also in these cases that such antipyretics as antipyrin, antifebrin, and phenacetin were indicated. A single large dose of antipyrin for the night—say ten to twenty-five grains—sometimes succeeded better than many smaller doses.

As a rule, salicylate of sodium hastened disappearance of pain and swelling, but it ought not to be tried longer than from three to five days. Sulphate of quinine was sometimes indicated. Alkaline salts or mineral waters were called for, as Vichy, bicarbonate of sodium, or one of the nitrates. Vegetable acids had been warmly recommended by some. Iodide of potassium and sodium had been justly highly commended, particularly where there was a tendency to chronicity. Remedies which had been administered for a specific effect in the rheumatism of children were not to be relied upon.

Gonorrhœal rheumatism was not sufficiently rare in children. When present it was usually in the knee, ankle, or shoulder. The effusion was likely to be purulent and excessive in amount. The treatment was more local than in ordinary rheumatism. Puncture might be made to ascertain the nature of the effusion. If there were pus, it might be removed, the cavity washed, and thoroughly disinfected. Then establish rest and apply gentle, steady pressure by bandage, with or without mercurial plaster or iodoform collodion beneath. Salicylate of sodium, or iodide of potassium and sodium, must be continued a long time.

After an attack of acute rheumatism small nodes or neoplasms, consisting of young connective tissue with numerous cells, might remain a few days or several months, but called for no special therapeutics. In that form of rheumatism in which there was a tendency to hemorrhage into the parts, cardiac stimulants were indicated early. Salicylate of sodium should not be administered, since it had a tendency somewhat to increase the hemorrhage.

Chronic articular rheumatism was rare in childhood. The treatment was about the same as in the adult. Salicylate of sodium was indicated only in acute exacerbations. The so-called hydropathic treatment, cold or hot baths, would prove beneficial. Local applications of tincture of iodine, iodoform collodion, etc., were called for. Much benefit was derived from alkaline waters. Dr. Jacobi recommended lithia water.

Muscular rheumatism could be diagnosticated occasionally in very young children; from six to twelve years of age it was not very rare. The symptoms did not differ much from those observed in the adult. The neck and back of the shoulders were most affected. The best preventive was the habitual use of cold water. The interrupted current was beneficial, as were also certain other remedial agents in individual cases.

Dr. William H. Thomson opened the discussion. He said his attention had been very early called to the etiology of rheumatism by the fact that while it was commonly attributed to cold and moisture, yet he had observed it to be quite prevalent among the inhabitants of the hot and dry desert of Syria. Gout, on the contrary, was to be found nowhere in Mohammedan countries. It was seen only in countries where alcohol in some form was used. On inquiring what there could be in common between the climate of Syria, for instance, and that of the north of Scotland which would account for the prevalence of

rheumatism in both of those places, he had arrived at the conclusion that the disease must be due to chilling of the skin when moist. In Arabia the heat during the day was intense, the inhabitants lay on the sand with inadequate cover during the night, the surface of the body, bathed during the day in perspiration, rapidly cooled, and rheumatism resulted. To show how great was the change from the temperature of the day to that of the night, his father had told him that he had never suffered so much from the cold as one night at the foot of Mount Sinai, when the thermometer during the day had registered 140° F.

Regarding the diagnosis of articular rheumatism, it was difficult to make, for all affections of the joints were apt to interfere with the functions in the same way. Diseases quite distinct in origin were often called rheumatism. An important point in differential diagnosis between rheumatism and gout was found in the pulse, it being soft and compressible in rheumatism, the contrary in gout. In scarlatinal rheumatism, however, there was an incompressible pulse, and with it there was often an enormous deposit of uric acid in the urine, sometimes pus, the affection approaching pyæmia. He was inclined to believe in an unknown function of the skin, which, when disturbed, led to a secondary product in the system which caused rheumatism.

He said Dr. Jacobi had alluded to the possibility of a connection between acute articular rheumatism and quinsy. He had himself seen some patients in whom an attack of quinsy was pretty sure to be followed within ten days by acute rheumatism. He had been able in nearly all cases to trace a connection between the rheumatic attack and chilling of the moist skin. That being so, he had a great fondness for the continued use of the warm bath in this affection. It acted as an anæsthetic, and rendered the urine alkaline. The skin should always be kept enveloped in flannel in rheumatic subjects. As a prophylactic he had for years prescribed oily inunctions, particularly on the back of the neck and shoulders. He also placed a great deal of reliance on cod-liver oil in chronic rheumatism. He fully shared the views expressed by Dr. Jacobi regarding carditis in the rheumatism of children, and warning against the likelihood of its occurrence even in mild cases. Particular care should be taken of children who showed any choreic symptoms. The growing pains referred to by the author led him to take precautionary measures, particularly in the administration of cod-liver oil, inunction of the skin, and the use of flannel underclothes.

A most violent rheumatic inflammation might be present in a joint and disappear within a short time, and leave no signs whatever of its former presence, a fact which was peculiar to this disease alone, yet in the heart permanent lesions were likely to result. He could partly account for this fact by the continued and rapid movement of the heart, it being much more rapid even than during health, and more rapid in the rheumatism of children than in that of the adult, while in the joints there was usually complete voluntary or involuntary rest or immobility. Because of the marked rapidity of the heart's action in the rheumatism of children, he gave aconite in full doses. Digitalis would not do so well as aconite in these cases. At the same time the blood should be rendered alkaline. The chest should be protected from cold air, and he would not allow the precordial surface to be exposed under any circumstances.

Dr. J. Lewis Smith said that during a practice of thirty years, or more, he had seen a large number of cases of rheumatism in children in private practice, but not having kept a record of them he would base his remarks upon the cases seen the past fifteen years at the Outdoor Department of Bellevue Hospital. He had diagnosticated seventy-eight cases in persons under fifteen years of age. In many of them, however, the diagnosis was based on the history and the presence of a heart-lesion. No case was under one year of age, few under two. He believed that rheumatism before the second year seldom showed much swelling by which it could be diagnosticated. He had seen tumefaction in tetany in babes six or eight months of age, which might be mistaken for rheumatism. In the vast majority of cases the rheumatism was in the lower extremities. The local manifestations were likely to be much less pronounced than in the adult. In some of the cases the parents had spoken of it as growing pains. The laity should be taught that there was no such thing as growing pains. Of his seventy-eight cases, forty-nine had distinct cardiac murmurs, and in many it was the cardiac disease that had led him to inquire for a history of rheumatism. In one child, aged twelve, an embolus of the brachial artery had led to lividity and coldness of the right hand. The parents said it had previously been troubled in the same way in the right leg. Most of the patients were seven to eight years of age, the vast majority between three and seven. It was very difficult to diagnosticate pericarditis if there were an aortic or mitral bruit to cover the sound. Enlargement of the heart was often present when the disease had lasted a year or more. The pulse was often 110 or even 150. As bearing on the relation between chorea and rheumatism, he said that during the same period (fifteen years) he had seen chorea minor in sixty-seven cases, in only eighteen of which was he able to assign rheumatism as a cause. There were certain reasons why the profession should yet hesitate to accept the microbic origin of rheumatism.

The important practical point was to make an early diagnosis and prevent heart disease. He had been in the habit of administering salicylate of sodium or salicylic acid in some form, and believed by thus cutting off an attack cardiac disease might often be avoided. He applied it to the parts also.

Dr. H. D. Chapin thought that while it had come to begenerally recognized that rheumatism was not an uncommon disease in children, yet it was very difficult to diagnosticate. There was no pathognomonic symptom. One had to judge rather by what might be called the composite of the disease; by the presence of pain, which was likely to exist in the fascia as well as the joints, by endocarditis, by the profound hydræmia which he thought was generally present, and by chorea. The pains were likely to first attract attention, yet a child often had pains in the legs due to over-exercise and not to rheumatism. Unlike in rheumatism, however, they were not so likely to have pain on rising in the morning as after retiring.

He quite agreed with what had been said as to the need of rest in endocarditis. The mistake was made in allowing the child to go about too soon. He had found tonsillitis in connection with rheumatism too frequently to be accounted for as a mere coincidence. He had diagnosticated rheumatism in one child of eleven months. It began in the elbow, went to the knee, then to the neck. In treatment he sought to stop intestinal fermentation and promote action of the skin. He gave hot alkaline baths, had flannel worn next the skin, regulated the diet, gave cod-liver oil, in many cases iron, and thus sought to prevent recurrence of the attacks.

Dr. August Seibert had counted his cases at the dispensary in 1888, and at that time had found rheumatism in thirteen children under one year of age. He had seen the disease occur in children first, then in the mother and father. He had for years been disposed to look upon rheumatism as an infectious disease. It occurred where sanitation was poorest; wherever there was filth and dirt there also was inflammatory rheumatism. The same was true of other infectious diseases. The best remedy was salicylate of sodium; its action must be in doing away with the germs of the disease. He administered it in children by the rectum, thus avoiding stomach and cerebral symptoms.

Dr. John C. Peters thought the rheumatism occurring under the conditions referred to by Dr. Seibert might be accounted for by cold and damp, and want of sufficient underclothing. He was disposed to account for it in that

way rather than by infection. He placed great reliance on alkaline baths.

Dr. August Caillé thought the evidence favored the view that rheumatism was surely an infectious disease. Ever since he had so regarded it, he had considered in what way it had entered the system. Those who had spoken to-night had mentioned its frequent connection with sore-throat, and he was disposed to believe that that was one of the channels through which it entered the system.

Rest was essential in treatment, yet it was very difficult to obtain in children. The indication in the use of drugs was to neutralize the poison in the blood. Alkalies increased the alkalinity of the blood and were beneficial; antiseptic chemicals were good. To prevent heart complication he gave a cardiac sedative, and also applied an ice-bag over the præcordium. He was very sanguine that within a reasonable length of time the chemists would find even a more efficient antiseptic remedy than those now used with which to counteract the poison of rheumatism.

NUISANCES ON THE CROTON-WATER SHED.

Dr. John C. Peters presented the report of the State Board of Health on the Croton water-shed, showing the necessity for abating the rapidly increasing nuisances in the region whence the city obtained its water supply, and, on motion, resolutions were adopted appointing Dr. Peters, the President, and the Secretary of the Society a committee to wait on the Mayor and Aqueduct Commissioners, and urgently request them to enforce the law in this respect.

## Correspondence.

### ELECTROLYSIS AND THE RADICAL CURE OF STRICTURE—WHY THE CHALLENGE HAS NOT BEEN ACCEPTED.

To the Editor of The Medical Record.

Sir: So many inquiries have been received by us in regard to the progress of the trial of electrolysis in the radical cure of urethral stricture, that we feel called upon to present a statement of how the matter stands, especially as there is an erroneous impression prevalent that our challenge was accepted.

We have had three meetings with Dr. Newman, who, after much amiable discussion, declines our challenge on the following grounds:

1st. That he is unable to obtain fair play in New York.

2d. That he objects to the use of dispensary patients.

3d. That he objects to either party interested furnishing the patients.

He offers, however, a counter-proposition, viz., that the trial take place in Philadelphia. That the patients be furnished by some disinterested party in that city, and that the committee consist of one member from New York, one from Philadelphia, and one from Baltimore.

In regard to the Doctor's inability to obtain fair play in this our city of New York, we must leave that for the profession to judge, stating, however, that the names of the gentlemen who had consented to act on the committee, if so requested, comprised those of Drs. Weir, McBurney, Bangs, and Abbe.

In regard to the second objection, we were unable to provide ten private patients who were willing to become the subjects of the experiments; nor (third) have we been able to discover any disinterested party who is willing to do so.

The Doctor's proposition we must decline, not only on account of the imputation on the profession such acceptance would imply, but also on account of the practical impossibility of making the constant trips to and fro which such trial would necessitate.

While regretting the outcome of this endeavor to prove or disprove the efficacy of electrolysis in the cure of urethral stricture, we cannot but feel that, to those of a logical turn of mind, at least, our effort has not been wholly fruitless.

Respectfully yours,

George E. Brewer,
William K. Otis.

### RÉSUMÉ OF THE EXPERIENCE OF SEVENTEEN YEARS IN THE OPERATION OF DILATING URETHROTOMY.[1]

BY FESSENDEN N. OTIS, M.D.,

CLINICAL PROFESSOR OF GENITO-URINARY DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; CONSULTING SURGEON TO CHARITY HOSPITAL, ST. ELIZABETH'S HOSPITAL, THE MANHATTAN EYE AND EAR HOSPITAL, ETC.,

THE operation of dilating urethrotomy, for the removal of urethral stricture, as devised and practised by myself, has now been before the medical profession for nearly seventeen years; the first dilating urethrotome, with a brief report of six cases upon which it had been used, having been presented at a meeting of the New York Medical Journal Association, November 24, 1871.

Previous to that time internal urethrotomy, as a rule, was performed only as a last resort, in cases when gradual dilatation was for some grave reason deemed impracticable, or when only very temporary relief had been obtained by that method.

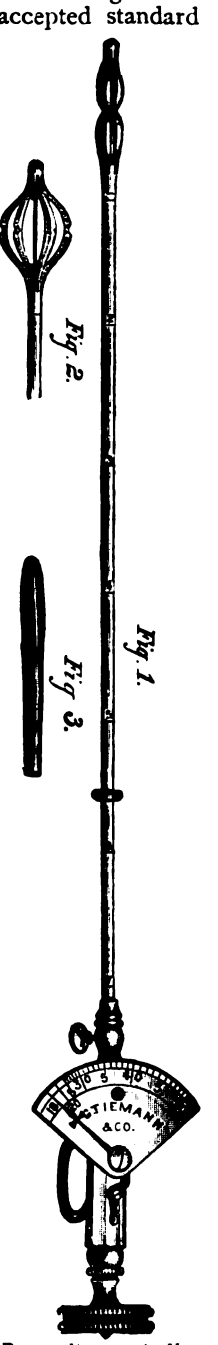
In the performance of internal urethrotomy, at that time, there were no fixed principles established for the guidance of the surgeon, as to the extent of the incisions.

The standard urethral calibre accepted by all authorities was then 21 mm. circumference (French scale), or No. 9 of the English scale, beyond which sizes no necessity for interference, on account of symptoms, was recognized. The individuality of the urethra had not been discovered, and urethral instruments for the most extreme dilatation, as for the over-distention of stricture, did not exceed 30 mm. in circumference; while 21 mm. was considered sufficiently large for use in all ordinary practice. The permanent cure of stricture by dilatation, by divulsion, or by division was not effected nor expected, and even the possibility of a radical cure, by any method, was denied by all accepted authorities. Under this condition of things, dilating urethrotomy was proposed. It was based upon the acceptance, first, of an individual calibre for every urethra; second, upon the alleged necessity (in order to secure the best results) for complete division of all presenting stricture up to the normal urethral calibre; this point to be ascertained by actual measurement in each case.

This was at first determined with difficulty, and only approximately, by means of accurately graded metallic bulbous sounds. Subsequently, however, with increased ease and precision, through the urethrometer which was presented by me to the profession in 1874. Through the use of this instrument, after a time it became apparent that a proportionate relation existed between the size of the flaccid penis and the normal urethra in any given case, and this fact was subsequently found of much value in estimating the normal urethral calibre, in cases where no instruments for actual measurement were attainable.

Through the use of the urethrometer, also, the external urethral orifice, which had early proved a serious obstacle in ascertaining or estimating the normal urethral calibre (especially as it had been previously accepted as a guide to that calibre), was found to be of varying size (independently of the urethra associated with it), except in its perfect development, when it was then found to correspond completely in size with that of the canal behind it. Further observations soon made it evident that contractions of the orifice were capable of producing troubles similar to those caused by stricture farther down the urethra.

The importance of recognizing the various degrees of contractions between the previously accepted standard (*i.e.*, 21 F. or 9 E.) and the normal calibre, as ascertained by actual measurement, was made more evident as the study of stricture troubles under these new conditions was proceeded with. It was found, notably, that gleet, which had from time immemorial been considered the opprobrium of medicine and surgery, was, in certainly a large proportion of instances, dependent on the presence of urethral strictures usually of large calibre, not readily detected in ordinary examinations. The urethrometer, which was the outcome of a necessity for definite measurements (in order to use the dilating urethrotome with accuracy), thus broadened its own field to an extent little expected when its use was initiated. Through the division of strictures, often but slightly diminishing the normal urethral calibre (previously recognized as frequent in cases of gleet), it was found that in some cases the gleet disappeared without other treatment, and thus its dependence upon the stricture for its continuance was finally demonstrated. It was also found that the method of operation upon a stricture made tense and thinned by dilatation required a much less extensive incision for its complete division than when flaccid, and that in thus dividing it there was a marked immunity from serious hemorrhage, from urethral fever, from abscess, pyæmia, etc., which had been considered sources of danger in internal urethrotomy when complete division of the stricture was contemplated.



Present Form of the Urethrometer.

In the experimental experience of the first years (1871, 1872, and 1873) with the dilating urethrotome, the grave responsibility of so radical a departure from previous methods was not underestimated. The attention of eminent surgeons was invited to the procedure, and their presence secured at many of the operations.

Frequent reports of progress were made to societies, and every available opportunity was accepted to demonstrate in public and in private, at home and abroad, the method of operating, and from time to time to present for examination cases upon which the operation had been performed.

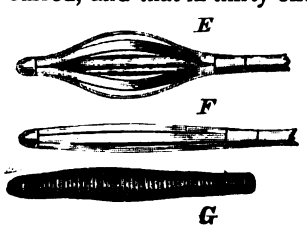
The new instruments, which at first were of necessity more or less crude in design, as well as in manufacture,

[1] Read before the Association of Genito-Urinary Surgeons, Washington, September, 1888.

were studiously modified and simplified, until, by 1874, it may be said that they were brought to a condition of satisfactory efficiency, and the operation of dilating urethrotomy—already having received much attention, and some practical acceptance, from surgeons in our own country, as well as in various parts of Europe—was now fairly launched into the field of genito-urinary surgery. The approval and the adoption of the operation necessarily implied abandonment of the old views of urethral proportions, and an acceptance of the individuality of the urethra with a normal calibre of from 30 to 40 mm. in circumference, and an average of about 32 mm.

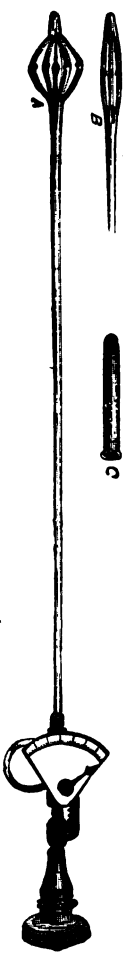
After the experience of another year, with the operation and its results (a report of one hundred tabulated cases, comprising division of 258 strictures, having been presented by me at a meeting of the New York State Medical Society in March, 1875), it was thought not too soon to make a distinct statement of the claims of dilating urethrotomy for precedence over the usual methods of internal urethrotomy for the treatment of urethral stricture; as well as those by divulsion, and (in the greatest majority of cases) over the plans of gradual dilatation. For all strictures anterior to the bulbo-membranous junction I insisted, first, upon a necessity for acquiring knowledge of the normal urethral calibre before any operative measures were instituted, and of the exact locality and size of every stricture in a presenting urethra; second, that there should be an accurate adaptation of surgical procedures to the individual strictures, with intent to remove them through complete sundering at some one point. Claiming this to result (when the division has been completely effected), first, in the complete removal by absorption of strictures so divided; second, greatly diminished total risks of operative measures, as compared with attempts at more or less complete removal of strictures by any other method.

In my first report of one hundred tabulated cases, comprising two hundred and fifty-eight strictures operated on, it was shown that no deaths or grave accidents had occurred, and that in thirty-one re-examined, two over three years, and three over one year after operation, freedom from every trace of stricture was demonstrated. From this fact the possibility of a radical cure of stricture was then asserted. Since that time, March, 1875, the claims which were then squarely and earnestly made in favor of dilating urethrotomy have found full corroboration and steadily increasing favor, so that here to-day there is no necessity of citing specific evidence of its general acceptance by the surgeons of America as a valuable surgical procedure. From what has come to my own personal knowledge, I am led to believe that many hundred operations upon strictures, by dilating urethrotomy, are performed in public hospitals, and also in private practice, in America, every year, and that the favor extended to it is steadily increasing; but, perhaps from the fact that it is no longer a novelty, and that there is but little credit to be gained from statistics which offer no new subjects for contemplation or discussion, the reports of these operations or their results do not find their way into the medical journals. It is because of this and also from the fact that, within the past year, already sixty complete cases of instruments for the scientific diagnosis of stricture, and for the performance of dilating urethrotomy by my method, have been ordered for use at the military posts of the U. S. Army alone; and further, that prominent surgical instrument makers have claimed increasing sales of my instruments to the profession at large; chiefly on these accounts, I have concluded that perhaps some of the results of a studious experience of my own in the use of these instruments might not be unacceptable. Especially has this seemed desirable for those whose previous opportunities have not been favorable for observation and comparison of results by different instruments, or of various modifications in the details of operations and after-treatment, and also who have not had opportunities of testing results after a long period from the date of operation.



Urethrometer with Springs.

In pursuance of this design, I also beg leave, first, to speak of some of the changes and improvements which have been made in instruments for diagnosis of stricture and operations by dilating urethrotomy up to the present time. After much experimentation the urethrometer, which was made originally (1874) with jointed metallic bars, was superseded in great measure, in 1875, by one made with steel springs, which latter had the advantage of giving a better shaped bulb, and could be made 5 or 6 mm. in size less than the former. It proved a very efficient instrument and, when well made, seemed to fulfil all the necessary requirements; but the difficulty of having it well made, especially as to the strength and temper of the springs, and its liability to rust and breakage, proved a source of much annoyance, besides involving much care and expense to keep it in good working order. A little more than a year ago, especially urged by the necessity of having a more enduring instrument for use in the military and naval service, I succeeded, through a competitive contest between the prominent instrument-makers of New York, in having a perfectly satisfactory instrument made, without springs and with a compass of from 18 to 45. This, when well made, lasts for many years, without the necessity for repair.



Original Form of Urethrometer.

Next, in regard to the dilating urethrotome. Since its first presentation to the profession in 1872 this instrument, through continued efforts for increased simplicity in construction and increased directness and accuracy in application, has necessarily undergone many modifications. One of these was fully twelve inches long, and *curved*, with an especial design to securing its more easy adaptation for the division of strictures at or beyond the bulbo-membranous junction. It was soon found, however, that while introduction into the curved portion of the urethra was facilitated, the dilatation by it, thus curved, was unequal, and could not be correctly indicated on the dial, thus rendering it unreliable. And what was a still stronger reason for condemning it, a further experience with dilating urethrotomy proved that division of stricture, by any form of urethrotome, beyond the bulb was unsafe and, in my opinion, distinctly not within the legitimate province of dilating urethrotomy. I have repeatedly condemned this long, curved, dilating urethrotome, in public and in private, to surgeons, students, and instrument-makers, for the last ten years; but in spite of my efforts they continue to be called for, and consequently to be made and sold; for which reason I take this especial opportunity again to condemn utterly this form of dilating urethrotome.

The one, and the only, dilating urethrotome I use and recommend for all operations of dilating urethrotomy is the short, straight instrument which I now exhibit, 8½ inches in length, circumference of shaft 16 mm., and capable of being expanded to 45, with a blade running 2 to 2½ mm. above the groove. I desire here to advise against the use of this delicate instrument as a divulsor, unless much more heavily made. When, in dilating strictures during operation, any undue strain is felt, it should be at once relieved by passing the blade through the stricture, then continuing the dilatation, and if necessary cutting again in a similar way until a dilatation of two or three millimetres may be made without marked resistance, a fact which, as a rule, indicates the complete sundering of the stricture. In cases where there is some uncer-

tainty as to the exact point of binding during the operation, the use of the bulbous sound will define it, saving unnecessarily long incisions. In regard to the locality of the incision, I do not hesitate to reiterate my former opinion in the strongest terms, that it should be always and only superiorly, *i.e.*, on the roof of the urethra, and as nearly as possible exactly in the median line. A more generous vascular distribution in the peri-urethral tissues will account for the fact that hemorrhage is more liable to be severe when the incisions are made inferiorly, and is a sufficient reason why inferior incision should be avoided.

Again, when the tissues are subjected to the tension necessary to secure the complete sundering of more than usually deep or resilient strictures, when the knife is drawn through them, the incision may extend even through the fibrous sheath of the corpus spongiosum, and make an infiltration of urine into the adjacent cellular tissue possible. A number of cases of this, always grave, accident have occurred within my personal knowledge—one within the past year. This case I saw in consultation, on account of unusual hemorrhage, which continued after the operation; much swelling followed, which it was thought might be from blood-extravasation. Two incisions were said to have been made with the dilating urethrotome, one on either side of the urethra, for the division of several strictures. The urine was first drawn by catheter, but during the night following the operation it was passed voluntarily. Increase in the size of the penis was immediately noticed, and when I saw the case it was about two inches or more in diameter, and considerably distorted. Escape of urine into the cellular tissue had evidently taken place.

Immediate free incisions through the integument and superficial fascia, and release of the imprisoned urine, saved extensive sloughing, but when I saw the patient, several weeks after, he had a urinary fistula on the side of his penis, while several prominent points of stricture still remained in the urethra.

In dividing the strictures *superiorly*, and in the median line, the knife, if penetrating to a point beyond the sheath of the corpus spongiosum, comes in contact with the fibrous tissue joining it to the corpora cavernosa, which barrier affords the greatest security against accidents from incision in the median line, but to which deep incisions in all other directions are always liable.

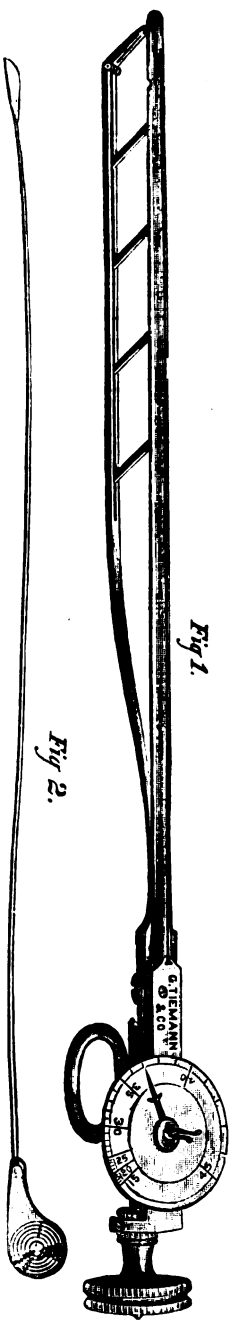


FIG. 1.—Cut of the Author's Improved Urethrometer.
FIG. 2.—Cut of the Curved Urethrometer, condemned as unsafe and otherwise unfit for use.

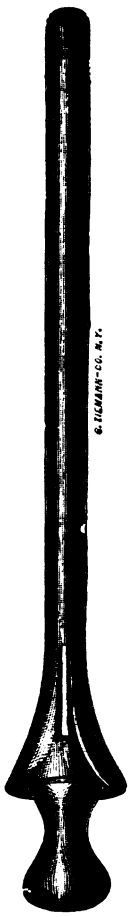
I believe that one important reason why the operation of dilating urethrotomy, in my hands, has been so uniformly successful, and so uniformly free from untoward results, lies in the fact that I always divide the stricture on the superior surface of the urethra, and as nearly as possible in the median line. Up to the present time, as I have stated, dilating urethrotomy has, in my hands, proved an eminently safe operation.

At the meeting of the International Medical Congress, held in London in 1881, I reported six hundred and sixty-four operations of my own without a death, or permanent disability of any sort. My operations since that date will swell that number to more than one thousand, and not only have I never yet had a death resulting, when the dilating urethrotome alone was used, that is, when it was not preceded by the use of the urethrotome of M. Maisonneuve, or its equivalent, but I have never yet seen an abscess, nor an escape of urine into the tissues, nor an attack of pyæmia, follow the operation. I believe another prominent reason for the safety from accidents which has attended my operations will be found in the scrupulous care of instruments, securing absolute cleanliness and asepsis as far as possible, and in the use of all available antiseptic precautions, for patients and instruments, both before and after operation; washing the parts externally with a solution of the bichloride of mercury 1 to 1,000, and using injections of boric acid internally, two or three times a day, until healing is complete; using the catheter for emptying the bladder, for the first few days after operation, whenever it is well borne, chiefly as a preventive of urethral fever; but in certain cases, where the urethra is very sensitive and intolerant of its use, allowing the patient to pass his own urine from the outset. I am a believer in the power of quinine and morphine to prevent urethral fever, in many cases, when contact of urine with freshly made urethral wounds cannot be avoided, and am accustomed, in such cases especially, to administer a suppository composed of ten grains of quinine with one-quarter grain of morphine, immediately after operation.

And now, in regard to the accidents of hemorrhage. When incisions are made beyond three inches, I take the precaution of having the perineal crutch[1] in position immediately after operation, so that, should hemorrhage occur subsequently, the patient can readily bear down upon it, and thus be promptly secured from any leakage back into the bladder. Effective pressure may be made at any desired point anterior, and thus always prevent any considerable loss of blood in any case. In cases where hemorrhage is not completely controlled by temporary pressure, I have found nothing better than the introduction of my hard rubber endoscopic tube, formerly recommended; any necessary counter-pressure being made by bandage. This may remain, if necessary, for two or three days, removing the tube only for cleansing; urination being readily effected or catheter passed, through it, on removal of the obturator. Cases requiring these unusual measures have not occurred, in my experience, in more than one-half of one per cent. of cases operated on. As a rule, to which there are very few exceptions, but slight inflammatory action follows even the most extensive incisions of dilating urethrotomy, although there is, as a rule, a pre-existing more or less acute urethritis in every case operated on; on the contrary, this is usually lessened, and the sensitiveness diminished. There is, however, in some instances where there is much sexual irritability, increased tendency to erection, more or less plastic exudation in the immediate vicinity, resulting in more or less troublesome chordee. The exudation causing this, as in gonorrhœa, usually passes off in a few days, unless the irritation is kept up and increased by some extraneous influence, such as a previously existing acrid discharge, sexual excitement, or too frequent or rude introduction of sounds. In such cases adhesions between the mobile layers of the peri-urethral fascia may occur, which, unless accidentally broken up by strong erections, may remain for weeks and even, in some cases for many months; sometimes a source of great annoyance, but finally passing off completely without any special treatment. In a former account of such cases,[2] I recommended a diagonal incision across the superior wall of the urethra, at the most salient point of incurvation; an operation which, at my hands, met with

[1] See Otis on Stricture of the Urethra, its Radical Cure, p. 283.
[2] Otis on Stricture, pp. 290-291. Putnam's Sons, New York.

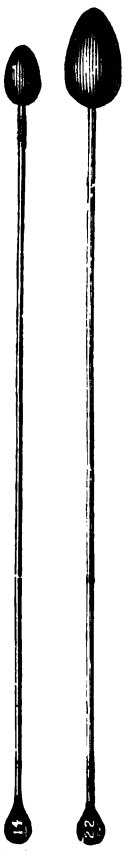
success in several instances. Subsequently, however, I adopted the plan of a mercurial inunction at the point of adhesion, which gave slow but finally satisfactory results. Within the past year, however, I have combined this with systematic, gentle massage, on a short sound, for ten or fifteen minutes daily; always falling short of producing tenderness. The results of this plan have already proved its capacity to remove the most pronounced troubles of this sort within a few weeks. Extension of the penis upon the sound, to as nearly as possible its full length, every day or two after the operation, has seemed to me serviceable in preventing such adhesions.



Author's Endoscopic Tube.

One point in connection with the operation of dilating urethrotomy which has been the source of much discussion and of some animadversion may, perhaps, be briefly considered to advantage at this time. This is in regard to divisions either of congenital or acquired contractions of the meatus urinarius externus. The experience and the study given to this matter, since my early discussion and advocacy of this procedure in 1875, have only confirmed the views then presented. The necessity of repeated passage of sounds of the full normal calibre of the urethra, subsequent to the complete division of stricture, in order to secure a permanent cure, renders enlargement of the orifice to that extent essential. This can rarely be done without unwarrantable violence, except by incision. Contractions at the meatus, congenital or acquired, have been also proven to initiate and prolong gleety discharges, and to be a source of various more or less important reflex difficulty throughout the genito-urinary tract, and not infrequently involving some of the spinal centres. Anything short of a complete division of the contracted orifice, up to the full normal urethral calibre, is usually insufficient to give the desired relief in such cases, and, if skilfully and judiciously performed, the operation is, in my belief, absolutely free from all reasonable objection, with results productive of more prompt, complete, and lasting benefit to the patient, and more satisfaction to the surgeon, than any operation of like gravity in the entire range of surgery.

The charge that has been made against it, that it diminishes the sexual power, I believe my experience with the operation justifies me in asserting, is wholly groundless; the fact being, on the contrary, that, in cases of sexual weakness, strictured meatus I have not infrequently found to be a prominent factor in inducing it, and the judicious division of the contraction one of the most potent measures in its relief or cure. That occasional irregularity of the stream has resulted from unskilful division is true, and that the apparent force of the stream has been diminished, in rare cases, is also quite true. There is no excuse for the former with a fairly skilful surgeon, and in the latter case, when it is remembered that the propelling force is in the bladder, and not in the urethra, it will be seen that such division could only affect the stream slightly, and then only when the propelling power of the bladder was, by a previously existing atony, reduced to the minimum. I have reported a case where the urethral orifice was divided, for the relief of grave reflex troubles, to 40, in a urethra of normal calibre 34, giving complete relief to those troubles, which resisted repeated lesser incisions, and where subsequently the patient (now an eminent medical man) became the father of several children; and with the meatus of this enormous size, he is able to propel his urine in an unbroken steady stream fully three feet. In this connection I would suggest that the dilating urethrotome should, in my opinion, never be used for the division of contractions within half an inch of the orifice, and that incisions for that purpose should be made with a straight blunt-pointed bistoury, and always on the *inferior* aspect or floor of the urethra, except where the meatus is placed so low that it is impossible to get sufficient room for the passage of the proper sized sound without incising the superior also. This for the reason, chiefly, that incisions superiorly in the glans recontract quickly, or, if they do not, absorption of the tissue of the glans may occur in the line of the incision, if at all extensive, which may result possibly in a distinct cleft; in one such case that came under my observation, some years since, giving the appearance of a bifid glans. The enlargement of the orifice should never be made by a sudden, quick stroke of the knife, as it is sometimes the custom of surgeons to do, but under cocaine or ether, very deliberately, and by repeated careful incisions, always downward and exactly in the median line, until by repeated trial with the bulbous sound the precise size required is attained. Should the frænum be in the way, if broad and flat, the incision may be carried through its centre as far as its base; if narrow, it should be snipped away to the same extent. When the meatus is situated too low to allow sufficient room, the surgeon must content himself with an inferior incision that shall not encroach upon the true floor of the canal, and will have to use the urethrometer, or its equivalent, instead of the sound, for keeping the sundered ends of the strictures from uniting until healing of the incision is complete. And now I wish to speak, lastly, of my experience and belief in regard to the permanence of results in dilating urethrotomy; that is, as to the validity of the claims which have been made for the radical cure of stricture of the urethra by this method of treatment. It is not unusual for surgeons to infer that cases treated by various methods, and apparently cured, are really so when they do not return to them for treatment. This proof, however, will not suffice where the radical cure of stricture is claimed.



Author's Bulbous Bougies.

A re-examination, with the bulbous sound, of the full size of the predetermined normal urethral calibre, after many years, will alone give the necessary proof upon which such a claim can be sustained. The acknowledged failure of all methods, except that of dilating urethrotomy, to wholly and permanently remove the stricture-tissue is accepted by those without an ample experience in this, as a sufficient evidence that radical cure of stricture is impossible by any method. Even Sir Henry Thompson says,[1] the more freely he divides stricture the more permanent are the results; that he has never had trouble from cutting stricture too freely, while he has often had occasion to regret having cut too little; and that he has frequently seen cases where relief has continued for years after internal urethrotomy. Yet he says, "I question very much if I have ever seen a case which has been completely cured by any treatment whatever." Under such a weight of testimony adverse to the probability of the radical cure of stricture, proof of facts claiming this for dilating urethrotomy must be full and conclusive. Preliminary to the production of such proof, it may not perhaps be out of place to call attention to the important fact that by no other method than dilating urethrotomy is complete sundering of the stricture at some one point insisted on; that upon the accomplishment of this, whether by means of the dilating urethrotome or by any other instrument, or by repeated operations, possibility of a radical cure

[1] Some Important Points Connected with the Surgery of the Urinary Organs." Student's Edition, 1884.

solely depends; that occasional failure to secure against the return of stricture, after the operation of dilating urethrotomy, does not disprove this position, but simply indicates a miscalculation on the part of the surgeon as to the depth and extent of the incision required, resulting in a failure to completely sunder the stricture. The only exceptions I have met have been very rare, and apparently due to the extension of the stricture-tissue beyond the reach of any incisions which could be safely made. The first really confident claims for the capacity of dilating urethrotomy to bring about the complete and permanent cure of stricture were made in 1875, and were based upon the results of thirty-six re-examinations with the bulbous sound of the full size of the normal urethra, at periods varying from six months to three years after the operation, during which interval no use of sounds had been resorted to. In 31 of these cases, or about eighty per cent., *complete freedom from the former strictured condition was demonstrated*, by the unobstructed passage, to and fro throughout the entire urethra anterior to the bulbo-membranous junction, of a metallic bulbous sound of the full normal size of the urethra, as determined at the time of operation. In a second series, consisting of 136 tabulated cases, presented in 1878, 82 re-examinations were reported; out of which 67 were found entirely free from stricture. In 3 of these cases six years and six months had intervened between the date of operation and the re-examination; in 2 cases, over five years; in 3 cases, over four years; in 10 cases, over three years; in 7 cases, over two years; in 20 cases, over one year; in 10 cases, over six months.

Besides these, 2 cases were reported in the second edition of my work on "Stricture of the Urethra," operated on in 1872 and in 1880 re-examined, and then, over eight years from date of operation, found to be free from stricture. In the first case, five strictures were originally present, the smallest of a calibre of 22 French. In the second, there were also five bands of stricture operated on, the smallest, 16 French. In addition to these cases was one operated on in March, 1875, for four strictures, defined by a bulb of 24 mm. in circumference, in a urethra of normal calibre, 36 French. This case was re-examined in May, 1880, and found completely free from all stricture by the easy passage of a No. 36 bulbous sound—five years from the date of operation, and no sound, bougie, or other instrument of any sort introduced during the interval. Again, in 1881, 2 cases presenting a long interval between operation and re-examination were met; the first seven years, the second eight years. In the first, strictures, four in number, were divided from 27 to 36 French. In the second, there were six strictures, ranging from 24 to 30, which were divided to 38.

Another case, operated on in May, 1871, re-examined in 1883, the longest interval then on record, showed complete cure of stricture by dilating urethrotomy, over twelve years after the date of operation. During the past summer I have had extracted from my case-books, and carefully tabulated, a third series of 420 cases, in which the normal calibre of the urethra, the size, number, and locality of the strictures are recorded, with the results of re-examination in 62 cases.

Recontractions were found to have taken place in 7 cases of strictures situated posterior to one inch, while at or near the meatus recontractions had occurred in 11 cases. I have recently had an opportunity of re-examining the case first operated on by dilating urethrotomy, and for the complete division of whose strictures the dilating urethrotome was originally designed. Extensive stricture was present, which had failed to be permanently relieved by several years of treatment by gradual dilatation. Divulsion with the instruments of both Holt and Vollemier had been practised to the fullest capacity of those instruments, and recontractions, from that point to 24 of the French scale, had taken place, associated, as the chief source of annoyance, with a persistent gleet. By means of the dilating urethrotome the strictures were all divided up to 32 French. Subsequent re-examinations, on several occasions, at intervals of three or four years, were made with the bulbous sound No. 32, without at any time detecting a trace of former stricture, and the gleet disappeared within a few weeks after the operation. No instrument of any sort was introduced for dilatation or any other purpose, except by myself at the intervals just mentioned, for the purpose of examination alone. On the last occasion, May, 1888, Mr. A—— (whose case is fully described in my book on "Stricture of the Male Urethra"), came to me for consultation concerning a difficulty quite independent of stricture, but was induced to permit me to again examine his urethra. I at first introduced, as on previous occasions, a 32 bulbous sound, and was struck with the complete freedom from any holding at any point. I then introduced the urethrometer, turning it up to 34, two millimetres above the previously estimated normal calibre, and found that traction enabled me to draw it out at this size, thus demonstrating in the most perfect manner the complete absence of the former strictures and the radical cure of the case, as shown by entire absence of every trace of stricture fifteen years and ten months from the date of operation.

## THE RELATION OF DUSTY OCCUPATIONS TO PULMONARY PHTHISIS.[1]

By WILLIAM BUCKINGHAM CANFIELD, A.M., M.D.,
CHIEF OF THE CLINIC FOR CHEST DISEASES, UNIVERSITY OF MARYLAND.

The connection between dusty occupations and pulmonary consumption is a subject by no means new, but it is of especial interest to those who have much to do with diseases of the lungs. The pulmonary diseases caused by the different kinds of dust have received a variety of names, according to the character of the dust inhaled, but collectively they are all covered by the name "pneumonokoniosis." The pathology of these conditions was not clearly understood. They were spoken of as "miner's phthisis," "grinder's phthisis," even when their tuberculous nature could not be proven. Even after Koch's discovery of the tubercle bacillus, and the gradually improved classification of the other classes of lung diseases, there seemed to be some doubt whether these dust diseases were tubercular or not.

Most writers agree that the inhalation of non-tubercular dust can only produce non-tubercular disease of the lungs. Naturally the different kinds of dust, such as sand, coal, soot, slate, etc., when inhaled in large quantities, as by persons enclosed in a thickly laden, crowded atmosphere (unventilated mines, etc.), gradually overcome the action of the ciliated epithelium and penetrate to the alveoli of the lungs, whence they find their way, by their sharp edges, through the wounded epithelium, through the pseudo-stomata in the alveolar wall, or between the cells through the *Kittsubstanz* (Osler). Those that are not carried off, rendered homeless or devoured by the greedy phagocytes, remain in their subepithelial bed and cause an irritation, a determination of blood, inflammation, and resulting hypertrophy of the connective tissue of the lungs. There results then a fibroid condition of the lungs, a fibroid phthisis or chronic interstitial pneumonia.

This condition seems to be produced by all kinds of dust indifferently when inhaled in condensed quantities. Fagge[2] says that this condition is only tubercular when tuberculous matter enters; that the common occurrence of phthisis among miners is due to the crowded and unventilated condition of the mines and to the great heat which the miners must endure. C. J. B. Williams[3] thinks that the fibroid element seems to oppose a direct barrier to the growth and multiplication of the bacillus

[1] Read before the Medical and Chirurgical Faculty of Maryland, at its Ninety-first Annual Session, April 24, 1889.

[2] Fagge: Principles and Practice of Medicine. Philadelphia, Blakiston, 1886, p. 997 ff.

[3] Williams: Pulmonary Consumption. Philadelphia, Blakiston 1887, pp. 13 and 23.

tuberculosis, and in large tracts of lung-tissue which have been converted into this material, often not a bacillus can be detected. Moxon[1] says that when they are found it is because fibrosis has supervened on a tuberculous condition of the lungs. Watson Cheyne,[2] Percy Kidd,[3] Sir Andrew Clark,[4] and others have also failed to find them. According to Orth,[5] consumption is one of the rarest complications of miner's lung, and Kunze,[6] often examining the lungs of those engaged in a variety of dusty occupations, concludes that if tuberculosis is present it is almost an accident, or was present before the patient began this occupation. The most recent literature on this subject may be found in the "Milroy Lectures on Occupations and Trades in Relation to Public Health," by John T. Arlidge, M.D. and B.A., London.

Although a fact founded on one case, perhaps imperfectly reported, may be of little value, I have thought it worth while to relate the following case:

CASE.—J. M——, Welshman, aged fifty-six, was admitted to hospital about February 1, 1888, with the following history, imperfect on account of his want of familiarity with the English language: As a boy he had been well and had been in health up to two years before, in Wales, where he took a "cold," which, growing worse, entirely unfitted him for his work, which was that of a miner. On inquiring more particularly as to his occupation, he said that he had been employed for about fifteen years in the slate-mines of Wales, and that his particular work was to split the slate. He said that there was always slate-dust flying about in the air, but not in such quantities as in coal-mines. Upon questioning him further, he said that the slate-miners were frequently affected with a cough and profuse gray or blackish expectoration, and that they usually died from this cough at about fifty. He said their manner of coughing was very hard, and there was much wheezing and shortness of breath. Inspection showed a spare man, with large chest-cavity, but not barrel-shaped. On percussion, which was carried out with great difficulty, a possibly increased dulness was found over the right apex in front, and at the base behind. The left lung was slightly hyper-resonant from increased work. The vocal fremitus was not markedly different on the two sides. Auscultation gave coarse and fine mucous and dry sonorous and sibilant râles, with expiration and inspiration over the whole chest, the expiration being much prolonged, as in ordinary pulmonary emphysema. Cough and shortness of breath were the troublesome symptoms, as were shown in his anxious expression and in his entire inability to lie in the horizontal position. His expectoration had been dark and also grayish-black, but recently it was white or colorless, as it was when I saw him. In order to promote expectoration I put him on the following mixture:

℞. Ol. terebinthin ..... ʒ iij.
Mucilag. acac. ..... q.s.
Aq. cinnamomi. ..... ℥ ss.
Aquæ ..... q. s. ad ʒ vj.
S.: A tablespoonful well diluted three times a day.

But as it produced nausea I changed to the following:

℞. Ammon. muriat ..... ʒ ss.
Mist. glycyrrhiz. comp. ..... ʒ iv.
M. et adde:
Potass. iodid ..... ʒ iij.
S.: A dessertspoonful well diluted three times a day.

This seemed to remove the mucus, but the dyspnœa still continued, and the râles, though dryer, were just as audible as before. Dr. Fraser's article on "Dyspnœa in Bronchitis"[7] having just appeared, it suggested itself to me to use the nitrite of sodium, which resulted in alleviating much of the dyspnœa. During the whole time the sputum was examined for bits of slate-dust or pigment-laden cells, but they did not seem to be present. His diet was regulated, and his bowels kept open. The urine was tested before the turpentine mixture was given, and albumen was found, but later it disappeared.

A few weeks after he entered hospital the sputum was examined for tubercle bacilli, not because I expected to find them but because I had made it a habit to examine the sputum in every chronic case for them. They were found in abundance. Specimens of sputum were examined with care at short intervals, and the bacilli were always found in large numbers. This surprised me, as I had not thought the affection tuberculous, and had given a favorable prognosis. His family history was good. Now, however, I feared a bad prognosis. Notwithstanding this, he continued to improve under tonics, and returned later to Wales. I have heard from him within the last month, and he says he is entirely well. As I have examined the sputa for bacilli many times, I feel certain that I made no error here, and yet it seems to me rather peculiar in this case.

Dr. G. Hunter Mackenzie[1] says that the number of tubercle bacilli found in the sputa of any case does not seem to bear any reference to the severity of the case, and that a case may go on for years with an enormous number of bacilli found at every examination.

I think the points of interest in this case are:

1. The patient had no previous history of, or predisposition to, pulmonary tuberculosis.
2. He contracted a disease with which tuberculosis is supposed to be very rarely present.
3. He had tubercle bacilli in abundance in his sputa.
4. He reports himself entirely well.

## SULPHONAL: ITS DOSAGE AND EFFECTS.

BY A. G. BROWNING, M.D.,
MAYSVILLE, KY.

WITH the first introduction of this hypnotic I made some haste to procure it, having at the time an exceptional case which did not just respond to chloral, paraldehyde, the bromides, or others of its class. Since, have used it rather perseveringly, and, frankly, more to account for its erratic action—to ascertain, if possible, its fitting place, than from any real satisfaction with its behavior in any given case. I beg to cite:

CASE I.—Aged forty; plethoric; a *bon vivant* and paroxysmal *spreer;* plagued with insomnia and on the verge of delirium; no hypnotic would quite suit. Accepting positive assurances that sulphonal was absolutely harmless, I yet made my first dose only ten grains, repeating this every hour until forty grains were given. Net result within twenty-four hours—a fidgety, wakeful night, worse than before, with giddiness, nausea, and general wretchedness all the following day; "cuss words" for drug and doctor—a failure.

The following evening, at eight o'clock, gave aggregate of previous doses—forty grains—in one portion. For four hours he carried it off lightly, as if only so much flour; but at twelve he talked wildly, had tremors, finally becoming so ugly as to compel some restraint. Now gave fifteen grains sulphonal. Uproar continued till five next morning, when he dropped to sleep.

Called at 10 A.M.—Still sleeping profoundly—just how much so, did not care to test by disturbing him; wanted him to sleep.

Recalled at 3 P.M. Friends much alarmed. Patient could be aroused, but somewhat incoherent, and promptly lapsed into stupor; cyanosed, and some stertor; with help, came slowly around, but was confused, dizzy, and generally uncomfortable for two or three days—all the time sleepy and dull.

[1] Edinburgh Medical Journal, January, 1889.

At the time I knew nothing of the postponed action of sulphonal—nothing of its action in any way; but coming early or late, it was unsatisfactory. I agreed with patient when saying he would take no more.

Case II.—Young man, aged eighteen; feeble development, and anæmic always; troublesome insomnia; couldn't tolerate taste and odor of paraldehyde; afraid of chloral; bromides did not suit. Gave twenty grains sulphonal and, two hours later, twenty grains more; no effects, early or remote. Got forty grains early next evening; after four hours there was excitement, which by twelve midnight bordered upon delirium, with delusions, and what I regarded as peculiar, harassing and tormenting *priapism*. No sleep worthy the name during night or on following day, but instead, a condition of lethargy, with frontal headache, vertigo, muscular inco-ordination, mental depression. Patient described the situation as, "Beastly! infernal! Half-dead for sleep—all the time half-asleep, but never quite!" Wasn't himself for five or six days.

Case III.—Gentleman, aged forty-two; fairly healthy, but strung on wire; wanted the earth, and that in a day; did brain-work over midnight oil; broke down; got insomnia and all that comes of it; was neurasthenic. To prop his flagging energies he took some whiskey daily, and more beer; was an habitual but "genteel" drinker before suspecting it, or being suspected. The more he drank the less he ate, till, his starved nerves taking on a neuralgia, he was something of a wreck. I aimed to tonify him by the usual means—some physic, more food, less drink. In view of alcoholic factor, and to avoid other habit, put him on bromides and cannabis, which did very well. But he clamored for more, and I gave him sulphonal, thirty grains first night; negative results. Following night he got forty grains; in two hours, fifteen grains more. The night was passed in a prolonged wail for sleep—faithfully wooed, but never won! The ensuing day he was too depressed and confused for attention to affairs; his gait was staggering as if drunk; he had nausea, vertigo, and frontal headache.

Two weeks later, under protest, he took fifteen grains, repeated in an hour; the next night the same. It gave refreshing sleep, and he was charmed. The third venture was followed by the original trouble, intensified, and he would have no more of it.

Case IV.—Colored girl, aged seventeen; uncertain quantity, mentally and physically; had, from history, rung all the changes of hysteroidal trouble, from insomnia to delirium and mania, and back again. Had been a circulating medium from doctor to doctress—vicarious of the whole troublesome genus, coming my way in due course, or in obedience to the "fitness of things." Insomnia to the front, with lurking movements which looked to me choreic. Was generously asked to do what man had not yet done—make her sleep! The ground was pre-empted: she had taken every created thing save sulphonal. I directed twenty grains, and repeat in an hour. No one could tell me what she did; she did *not* sleep! Next evening, in a moment of humane weakness, I gave forty grains; in two hours, fifteen more. Visited her next morning; again, she hadn't slept, but was writhing, twisting, and grimacing with chorea, after most approved fashion.

Odds were against me in an impending riot, the wrath-centre being in my vicinity; discretion seemed all there was of valor, and I retreated in good order, under a vigorous charge of having given this girl "fits!" Maybe I did; was coming to think sulphonal could do anything, save putting a patient quietly to sleep. Later there was a reaction in sentiment, and I had satisfaction of seeing this patient get well while I was giving her bromides and arsenic. A pleasing coincidence, under the bellicose circumstances.

The four cases here cited will be seen to cover the differing conditions of plethora, anæmia, neurasthenia, and hysteria, pure and simple. The primary object in all was to induce sleep. Failing in this, the question presents, in how far did opposing conditions affect results? Or, favoring conditions ascertained, how estimate the dose in an individual case? I cannot answer this; the action of sulphonal has been, with me, so erratic as to leave no base for logical deduction; much like Hercules with his club, striking in the dark. This is not the total of my experience in its use, but *is* the average of results obtained. I find it uncertain in action in same individual, in same or differing doses, with no recognized condition clearly indicating or contra-indicating its use, as yet.

It would not be fair to say I have never gotten good results from sulphonal; it is only true that I have been most times disappointed. Together with its delayed action, and too frequent unpleasant secondary effects, I do not find it comparable, as a hypnotic, to chloral or paraldehyde; have had less experience with amylene hydrate. Possibly, when the place for sulphonal is found, sulphonal will be found to fill the place.

---

## CHRONIC LYMPHATIC ŒDEMA OF THE UPPER LIP, COINCIDENT WITH INTRANASAL PRESSURE.

By JONATHAN WRIGHT, M.D.,
NEW YORK.

In The Medical Record of September 8, 1888, I called attention to a train of symptoms caused by the firm pressure of the middle turbinated bones against the septum. A few weeks previous to this an article by Dr. Roe, of Rochester, dealt with the same subject. As far as I know, Dr. Harrison Allen, of Philadelphia, was the first to discuss the subject, and his paper in the *The American Journal of the Medical Sciences* for 1880 was overlooked by me until my attention was drawn to it. In these and other articles various symptoms—neuralgic, reflex, and obstructive—are mentioned. Since the appearance of my contribution I have seen a very curious, and, I presume, a very rare sequence of the pathological condition referred to. The case, I think, deserves recording.

Lizzie C——, aged fifteen, was referred to me at the Demilt Dispensary, by Dr. G. T. Elliot, for a large diffused swelling of the upper lip and left cheek. The patient was otherwise perfectly healthy, and her previous and family histories were good. When seven years of age she fell and cut the upper lip, which remained swollen for three months, when it subsided. Four years ago, when she was eleven years old, the lip began to swell again, and a month later she noticed some nasal obstruction, at times, on both sides. She was also troubled a good deal with toothache. In two or three months the lip had reached the dimensions which it presented on her application to the dispensary, having never abated nor increased during the four years. She had derived no benefit from the use of ointments. There had never been any pain or tenderness to pressure.

On examination it was evident that the upper lip was two or three times its normal size. It projected far out over the under lip, producing a marked deformity. The skin was smooth, somewhat tense, and had a natural color, except that on handling it easily became red. There was no pitting on pressure, nor was the blood-circulation apparently interfered with. The enlargement extended markedly to the left cheek, but very little to the right. An intranasal examination showed that the left nasal fossa was enlarged, and the septum deviated considerably to the right. The mucous membrane was atrophied in many places. The middle turbinated bone on the left side was displaced upward and inward against the septum, and along its free border there was a muco-purulent discharge. As the crown of the first molar tooth was decayed and gave evidence of defect at the root, I surmised that the trouble might be an empyema of the maxillary sinus. This afterward proved to be incorrect. She was given an alkaline nose-wash to use three or four times daily. At the end of a week she came back with some diminution

of the lip swelling, and the nasal cavity presented a better opportunity for observation. There was no more mucopurulent discharge. Far back and high up, the middle turbinated bone was seen impinging on the septum at about the junction of the middle with the posterior third, both ends of the bone being free. As it at first seemed a simple hypertrophy of the soft parts, the patient was directed to continue the alkaline douching. At the end of another week there was still further diminution of the lip and cheek swelling, and the hypertrophy of the mucous membrane had decreased somewhat, but it was evident that it would be necessary to remove the remaining portion by surgical interference. This was accordingly done with a nasal snare, and the fragment, as large as, and about the shape of the pulp of the middle finger, proved to be a hyperplasia of the mucous membrane. The douching was continued, and at the end of another week the lip and cheek had reached almost their natural outlines. At the seat of the former operation there was, however, a bony excrescence, the soft parts only having been removed. Judging that when this became recovered with mucous membrane the intranasal pressure would be renewed, the bony growth was removed by means of the snare and forceps. A microscopic examination showed hyperplasia of bone combined with rarefying osteitis.

This may serve as an illustration of how the bony cysts are formed which we occasionally observe in the turbinated bones, and which are described by Zuckerkandl. The hyperplasia of bone having advanced to considerable dimensions, a rarefying osteitis begins in the centre, and we soon have a cavity with rigid bony walls.

Six weeks or a month after the operation, when some thickening of the lip still remained, but luckily after the intranasal wound had healed, the patient was attacked with facial erysipelas, which spread all over the face and into the scalp, having begun in the region of the molar prominences. When this had subsided, which it did without intranasal treatment, it was seen that the lip was smaller than before. It is now five months since the operation, and, generally, the size of the lip is not noticeable, but occasionally is seen to be much larger than usual, though it never reaches its former proportions. The swelling of the left cheek has not recurred. The middle turbinated bone on the left side is free throughout its whole length, very little deformity having resulted from the cicatrization following the operation. The mucous membrane has a healthier look, and the nasal secretion is much less than formerly.

When we come to consider the nature and the cause of the long-standing labial hypertrophy in this case, we are confronted by the meagreness of the literature on the subject. For want of a better name I have called it chronic lymphatic œdema. Although it is probably of an entirely different nature, its essentially local character resembles somewhat the cases of circumscribed œdema described first by Dinkelaker[1] and Quincke,[2] and later by Jamieson,[3] Graham,[4] Matas,[5] Osler,[6] Smith,[7] and others. Their cases were acute, resembling urticaria somewhat. In most of the descriptions the doughy feeling of the skin and its transparent, watery look are spoken of. Their cases had a neurotic element, and the swellings occurred more often in the extremities, and were usually not confined to one region of the body.

More nearly resembling it were the cases reported by Major[8] at the last meeting of the American Laryngological Association. I regret that I have as yet seen only an incomplete report of Dr. Major's paper. They were erythematous and erysipelatous in character, and extended over comparatively short periods. They seemed to depend on intranasal pressure, and treatment directed to the nose relieved them. Other gentlemen present narrated similar cases. To one of these categories belongs a case of which I have preserved short notes.

A boy, aged fourteen years, employed at the time in Roosevelt Hospital, said that his father had died of erysipelas or gangrene. He himself had always been perfectly healthy until about eighteen months ago. At that time his nose began to swell occasionally, beginning at the tip and extending as far back as the bridge. This would last for two or three days and then disappear. His nose was often obstructed, but he thought that this had no relation with the external swelling. He was never troubled in summer, but in the winter it would occur every week or ten days. There never was any pain or constitutional disturbances with it. He has never had erysipelas nor rheumatism, although a medical man once pronounced the nasal affection erysipelas. Ointments always gave him relief (?). There was no itching. The nose looked red and hot, and there was considerable lachrymal congestion. The upper lip was slightly swollen. There was some hypertrophy of the mucous membrane, covering the turbinated bones, but no intranasal pressure; the rhinitis, being slight, had produced no extensive structural change. Intranasal treatment seemed to have little or no effect on the external condition, which lasted but a short time. This patient had later an attack of true erysipelas, from which he recovered, but since then I have lost track of him.

Dr. H. Lavrand[1] has reported a case of frequently recurring facial erysipelas, in a case of Tornwaldt's disease, which was cured by treatment directed to the post-nasal affection. I have seen a case of general dermatitis of the nose associated with nasal polypi and hypertrophic rhinitis, and also several cases of acne in the nasal and malar regions which were cured or greatly benefited by intranasal treatment.

It seems to me evident that in many of these cases the lymphatics must be the channel of communication between the external and the internal affections.

In the case of Lizzie C——, I see no other explanation. There was no neurotic element in the case, and erysipelas only occurred after the relief of the intranasal pressure. The anastomoses of the lymph-channels seem so complete that it is difficult to understand how pressure at any one point, or even over a larger area, could cause engorgement at a distant point. The little that is known about the nasal lymphatics does not help us very much. Simon,[2] in 1859, found that they formed a wonderfully close net-work of vessels, more abundant in the region of the cribrous plate of the ethmoid. They all communicate with those of the external wall, and form a very close network there in three places, viz.:

1. At the top of the superior turbinated bone.
2. Upon the external surface of the middle turbinated bone.
3. In the space anterior to this.

He, as well as Axel Key and Retzius, traced communications with the lymphatics of the subdural and arachnoid spaces. Communicating with the lymphatics of the face they enter glands in the neighborhood of the angle of the jaw—the deep carotid and cervical. Internally they terminate in trunks which pass close to the openings of the Eustachian tubes to join glands on the lateral wall of the pharynx (Quain, Gray, M. McKenzie). Clinically we have an illustration of the absorbing power of the lymphatics in the rapidly fatal course of nasal diphtheria.

While it will be noted that the pressure in the case reported was in the neighborhood of the lymphatic nidus spoken of by Simon, the abundant collateral supply would seem amply sufficient to prevent any local congestion outside of the nose, and yet the onset, course, and subsidence of the external swelling corresponded so closely with the

history of the intranasal pressure that it seems more than probable the latter was the prime factor. In nearly all the cases referred to there seemed to be some more or less definite connection with erysipelas.

## Clinical Department.

### A CASE OF CYSTIC GOITRE.

By GEORGE T. WELCH, M D.,

KEYPORT, N. J.

GOITRE is looked upon without much fear in the United States, so far as any tendency toward mortality is associated with it, and special operations are seldom required for its relief; but an occasional fatal termination awakens a vivid interest in the mind of the practitioner in all the known methods of combating and eradicating the disease. Excision of the thyroid gland is a proceeding so formidable that few surgeons have had the courage to undertake it, and in view of the probable advance of goitre from a benign to a malignant growth, the physician should prescribe, and insist upon the patient's carrying out, all the known alterative means at his command while the tumor is yet small and tractable.

After remaining stationary for a quarter of a century a goitre will at times suddenly take on a savage energy of growth, and the victim, long lulled into security, will awake to find his passive enemy now become as relentless as any Thug in India. Such a case recently came under my notice in the person of Mrs. C. W——, aged sixty-three, who consulted me in October, 1888, in regard to labored respiration, cough, and attacks of extreme nervous exhaustion. Her description of the symptoms attending these attacks was so similar to those of reflex asthma that I was inclined to call it by that name until I could discover the exciting cause. The patient was apprehensive that a goitre which she had might be the origin of the attacks, but as it had remained stationary in size since its development, more than a quarter of a century before, during her first pregnancy, I could not feel sure that this was the case. The tumor did not feel sufficiently fibrous and fixed to give the impression that it was of a malignant character, or that it was grasping the windpipe and producing stenosis. An examination with the laryngoscope was, however, unsatisfactory, and left me in doubt. A measurement of the circumference of the throat over the goitre was taken, and the patient was placed on a tonic and nervine treatment, with inunctions of compound iodine ointment over the surface of the tumor. She showed signs of improvement for a short time, but the next attack of dyspnœa was still more pronounced and alarming.

Thereafter the voice was either whispering, or hoarse and croaking in character, and evidently the pneumogastric nerve was encroached upon. Measurements taken from time to time showed increasing size of the goitre, the attacks of dyspnœa became more frequent, and at times death seemed imminent. On two occasions large amounts of atropine, $\frac{1}{100}$ gr. used hypodermically, alone rescued the patient, who appeared moribund at the time of the injections, but who slowly revived as the blood came flaming to the surface.

Of all external applications I was convinced the use of the ointment of the red iodide of mercury was most satisfactory. After several days' inunction with this, I discovered an obscure sense of compressibility, and with the hope of finding that a cystic goitre had been developed, I thrust a hypodermic needle straight into the tumor and drew out a few drops of dark-colored liquid which confirmed this view.

I determined now to operate on the goitre after the method of Mackenzie, and had made a small trocar and cannula with a collar to which tapes could be tied. Kindly assisted by Dr. Cook, of Holmdel, I thrust the trocar from below upward into the mass, after incising the skin, and withdrawing it, left the cannula in position, tying the tapes firmly at the back of the neck. About two ounces of grumous fluid escaped and the tumor collapsed somewhat, although the outer wall was quite thick. Two drachms of the solution of perchloride of iron were now thrown into the sac with a syringe, and the cannula was plugged up. After three days the stopper was removed, and the contents of the sac allowed to escape. I now found that the tumor remained enlarged upon each side, and conjecturing that it was multilocular, I introduced a blunt probe and broke down the walls, causing a further flow of dark fluid, when the injection of the iron solution was again used. At different times thereafter this had to be repeated, the sac filling up with liquid to its original size, but finally a complete cure was effected.

The patient remained weak for a time, but gradually improved in strength and spirits, and finally went to her home, twelve miles distant, early in January. There had remained some cough, of a spasmodic character, and examination of the throat with a laryngoscope now showed stenosis of the larynx, and led me to suspect further dangerous complications, which the sequel unhappily demonstrated; for, after four weeks of comparative comfort, the dyspnœa again took on a dangerous character, hectic supervened, the heart showed signs of failure, while, the cough and strangling efforts at expectoration became frightful to behold. All drugs were perfectly powerless to control the paroxysms, except chloroform and nitrite of amyl. Inhalations of cocaine, steam, etc., were tried in vain, while dressings of hot water or poultices were frantically torn away by the patient. Occasionally the happiest effect would be produced for a few hours by hypodermics of atropia, but the dryness of the mucous membrane of the throat which supervened would increase the suffocation.

The singular sound in breathing, together with the character of the product expectorated; the inflammatory swelling, recognized by the fitful glimpses to be had with the laryngoscope; the pain, cough, dyspnœa, dysphonia, and dysphagia concurred in pointing to necrosis of the cartilages of the larynx, and the prognosis was entirely hopeless. On the night of February 18th, after informing the family and husband that the end was in all probability near, and that nothing further could be done except tracheotomy, which might add to the days of suffering but could not cure the disease, I made an effort, after spraying the throat with cocaine solution, to lance what appeared to be an abscess in the larynx, but the most heroic efforts of the patient could not control the spasmodic cough long enough for me to succeed. I then tried to reach the part with a slender sponge probang dipped in a solution of chromic acid, and was rewarded by finding the patient breathed easier, and I retired about 11 P.M. with the intention of performing tracheotomy next day, should it seem called for; but shortly after midnight on February 19, 1889, the patient died peacefully in her sleep.

It is possible that early efforts at a cure of this goitre might have been entirely successful, but the physician whom this lady consulted eighteen years before recommended a do-nothing policy, and assured his patient that nothing would ever come of the goitre.

### SOME SUGGESTIONS IN REGARD TO TREATING GONORRHŒA.

By E. P. RICE, M.D.,

CHICAGO, ILL.

A GREAT variety of methods for treating gonorrhœa can be found in the very many text-books at our command, yet the average practitioner has not, as a rule, any very definite plan, not having given the subject generally any special attention. Among the thousands of readers of THE MEDICAL RECORD we will find undoubtedly an almost numberless variety of formulas in use; and, in view

of these facts, permit me to make a few statements in regard to the treatment of this very common disease, which may be the means of inducing others to try this plan. My attention was called to it, some three years ago, by a few remarks from a practitioner in Wisconsin, which appeared in THE RECORD. I thought favorably of the plan, and will give the *modus operandi* as I use it.

First, taking for granted that gonorrhœa is due to the action of a specific microbe, the gonococcus, we must treat it on the antiseptic plan, hence the following line of treatment. The patient should be placed in the recumbent position, and after lubricating an ordinary soft-rubber catheter with five per cent. carbolized oil, introduce it as far as the prostatic portion of the urethra. In acute cases it may be necessary to inject a little five per cent. solution of muriate of cocaine, if pain is produced. Now insert into the free end of the catheter an ordinary glass syringe, having a nozzle with an opening sufficiently large to allow the liquid to pass through easily, which will be about the consistence of an ordinary emulsion, and should be made as follows:

℞. Acid. boric..... ʒ iij.
Glycerini..... ..... ℥ j.
Mix, and rub well together, and shake well before using.

Pour about two drachms of this mixture into the syringe, having previously withdrawn the plunger. Now, gently insert the plunger, and force the liquid into the catheter, which is held in place with the thumb and forefinger of the left hand—the forefinger of the right hand should be used to force in the plunger. After all the liquid has passed out, gently withdraw the catheter, stripping it at the same time in order to force all the liquid into the urethra. Let the patient remain in the recumbent position for ten minutes longer, the whole operation lasting generally about fifteen or twenty minutes. This treatment should be repeated every day, for the first two or three days, and then on each alternate day. As a rule, in acute attacks, five or six treatments will suffice. In long-standing cases the same treatment should be used, alternating with some mild astringent injection, as Lloyd's hydrastes, used in the same way. The sound should always be used in subacute and chronic cases, at intervals of about three days. It is also advisable to give internally, in all cases, a saline laxative, and in the old cases I generally give, in addition, capsules of bal. copaibii, ♏ vj.; ol. cubebæ, ♏ iv., t.i.d., either before or after meals.

The fact of antisepsis should never be lost sight of, as so many are apt to do. It is a well-known fact that boric or boracic acid is a mild and unirritating antiseptic which, when combined with glycerine as a vehicle, also an antiseptic, renders it a very safe agent to use for this purpose.

One important point is also gained in this plan. We always have the patient practically under control, and can watch the progress made, not being dependent upon the say-so of the patient. I have used this method of treatment in quite a number of cases, with the very best results, and can unhesitatingly recommend it to the profession.

## PNEUMONIA TREATED WITH PEROXIDE OF HYDROGEN.

BY J. L. GREENE, M.D.,

RED CLIFF, COL.

ABOUT a year ago, after some study of the action of peroxide of hydrogen, it occurred to me that it might be well employed in treating the "high line," or congestive, and the croupous, or acute lobar pneumonias which prevail and are often very fatal in the Rocky Mountain region. Out of twenty-three cases treated by me since that time there have been twenty-two recoveries and one death. The death was in the case of a puny infant, eleven weeks old, and so far gone when first seen that any treatment whatever could avail but little. These cases comprise some with double pneumonia, some persons of robust habit, some with constitutions impaired by long intemperate use of alcoholic liquors, and several children ranging in age from three months to three years.

The main treatment has been the internal use of peroxide of hydrogen, though I have used any rational measures that were indicated to meet complications, or unusual conditions arising in any case. I have had but little use for either opiates or antipyretics.

The dosage mentioned in the rather scanty literature on the subject, as applicable to other classes of cases—teaspoonful three times a day—is far too light for pneumonia. In the high line, or congestive form, common enough at high altitudes, the patient would exhaust the effect of the first dose and die from apnœa before the second would be due. I have often given one-fourth to one-half a teaspoonful, well diluted with water, once in five to ten minutes for an hour or more, with good results. In acute lobar pneumonia I usually give half a teaspoonful, diluted, every hour, with benefit, even when no emergent conditions exist, and I continue it till after the crisis occurs. I am not aware that any one else has made a systematic use of peroxide of hydrogen in such cases, and I have had to feel my way in establishing a dosage adapted to my cases, which are possibly considerably influenced by peculiar conditions of climate and altitude.

Under this treatment the crisis appears to be a time of comparatively small importance, and a case taken early in the stage of engorgement can usually be aborted and the infiltration cleared from the lung.

I do not apprehend that these few cases will go far toward establishing anything; but if the method of treatment I have used, and outlined here, proves valuable in other hands I shall be satisfied.

## SEVERE SYMPTOMS RESULTING FROM AN APPARENTLY TRIVIAL INJURY.

DR. J. J. BOONE, of Mount Victory, O., reports the following case: "Elihu J—— had sustained an injury by running a small splinter of wood into the thumb, about half an inch from the end, on the flexor surface. On the following day, as it was giving him some pain, his medical attendant proposed to cut it out for him, which was agreed to by the patient, and he worked hard for about one hour to extract the splinter, though I do not know whether he got it out then or not. The case was placed in my hands from the fact that the patient's medical attendant had gone out of town, not to be back for a few days. On February 3d, the first time I had seen him during his sickness, and two weeks after the accident, his temperature was 103½° F., pulse 125, and he was so weak that he could not stand up, and could sit up only with great exertion, and was suffering great pain, with a tightly swollen forearm, hand, and fingers. Pus was discharging from the wound in the thumb. I dissected off the epidermis of the thumb, as under it was a layer of thick, greenish pus; then with an ordinary Davidson syringe, stretching a piece of one-eighth inch rubber tubing about eight inches long over the nozzle, I proceeded to wash out the abscess cavity in the thumb with a 1 to 2,000 bichloride-of-mercury solution, when I discovered a greenish-black spot, the size of a silver five-cent piece, between the distal ends of the metacarpal bones of the little and ring finger, on the extensor surface. I picked it up with a pair of forceps and cut it out without pain to patient; then, on use of syringe, I was enabled to inject the solution of mercuric chloride into the tissues of the thumb and have it come out where I had removed the piece of dead skin, carrying with it a large quantity of pus. The next morning I discovered another abscess between the distal ends of the metacarpal bones of the index and middle finger, on the extensor surface, which I opened, using the same solution as before. The solution was ejected from both new openings. In the evening I examined the arm carefully, and found evidence of an abscess midway between the wrist and elbow. Cutting in about

half an inch with a curved pointed bistoury, I was enabled to evacuate about four ounces of greenish-yellow pus; again washing out through the thumb, the solution came out through all three openings, carrying with it a large quantity of pus. Under the treatment of frequent cleansing with a solution of mercuric chloride about three times a day, in five days the swelling had almost gone, and the patient made a good recovery, although there is some stiffness in the fingers yet."

## Progress of Medical Science.

CONFLUENT SMALL-POX TREATED SUCCESSFULLY WITH SALICYLIC ACID.—In March, 1881, the *Bulletin de Thérapeutique* published an article in regard to the use of salicylate of soda in the treatment of variola. In the same journal of May 15, 1889, Dr. Baudon reports a case in which he made use of the same treatment (modified to suit the case) which he had formerly, in 1881, used so successfully. The patient, a woman, aged twenty-five, was supposed to have been vaccinated in early infancy, but no scar could be found. She had assisted at the burial of her two brothers, who died of variola, and after returning home she suffered from the prodromata of this disease. On April 4th the eruption appeared, and it quickly became confluent. The face became red, enormously swollen, and covered with pustules, which were everywhere confluent. Over the surface of the body, although more discrete, they were still large and numerous. He adopted the following treatment: Three times a day the face, limbs, and chest were to be covered with a pomade of one part of salicylic acid to twenty-five parts of vaseline. A powder of talc, one part; salicylic acid, twenty-five parts, to be then dusted upon the parts. Four grains of quinine to be given three times a day. Borated gargles for the throat. Milk was given as needed. The discharges were covered with quick-lime and buried. The soiled clothing was put into boiling water. The other occupants of the lodging-house were vaccinated and sent away. The body of the patient exhaled *no odor at all*, and, notwithstanding the severity of the eruption, the patient was almost free from suffering. On the 7th, delirium, of some hours' duration, set in. The swelling gradually subsided, and on the 12th he scraped carefully away the coating which had until then covered the parts, and found the skin smooth, without the least trace of cicatrix, supple, elastic, a little more red than normal, but entirely free from scabs. Recovery was complete, without any accompanying accidents, without those repulsive exhalations which make small-pox patients so disgusting and such dangerous sources of infection. This case is related by Dr. Baudon in a simple way, with the hope that it will prove useful. He believes that the treatment is rational, and that those who try it will find it a great comfort, if only in preventing the foul odors of the diseased body.

NEPHRITIS AS A SEQUEL OF WHOOPING-COUGH.—Dr. Mircoli, of Monterubbiano, has lately called attention to the occurrence of nephritis as a sequela of whooping-cough. In 1887, among ten children who suffered from the disease, the attack was followed in two by nephritis, which proved fatal in one of them. The necropsy left no doubt as to the existence of nephritis. In 1888, among thirty-five cases of whooping-cough, Dr. Mircoli met with nephritis in four; two of these died, and in one of them a post-mortem examination was made. The kidneys were seen with the microscope to show severe parenchymatous nephritis. No cultivation experiments could be made to determine whether the disease was parasitic or not. The microscope showed no trace of micro-organisms.—*British Medical Journal.*

SPLENIC MURMURS.—In a recent paper, Professor Bouchard drew attention to the existence of a bruit over the region of the spleen in cases of enlargement of this organ —a bruit not attributable to pressure upon vessels or to conduction from the heart, but apparently generated in the splenic artery or in the spleen itself. During the past three years he has constantly practised auscultation of the spleen, and on five occasions has detected such a bruit. Three times the splenic enlargement was due to cirrhosis of the liver; in one case the spleen was hypertrophied, as in leukæmia, but the blood was not altered; and in the other the swollen spleen was associated with a large liver in an obese subject. In several cases—notably in malarial spleen and in one marked case of leukæmia—no bruit was to be detected. He entered into details of his first case—one of cirrhosis of the liver—in which the spleen was very large, measuring seventeen by eleven centimetres (about 6.3 by 3.9 inches), and was hard and smooth. Over its whole area there was audible a soft, prolonged bruit, synchronous with the pulse, but the bruit could not be traced beyond the splenic region. It was still audible when the patient was made to lie on the left side, to prevent the organ exercising any pressure upon the abdominal vessels. The bruit was audible whenever the patient was examined during the three years the patient was under observation. The case was otherwise interesting as an example of "cured cirrhosis," upon which the chief discussion took place. There had been considerable ascites, which required paracentesis on three occasions; but Professor Bouchard attributed the arrest of the disease to the prolonged administration of calomel in small doses. The patient also had an attack of uræmia, which was successfully treated by naphthol, on the theory of intestinal antisepsis being needed to limit the operation of auto-intoxication in the production of the uræmia.—*The Lancet.*

THE WAYS AND WANDERINGS OF THE CONTAGION OF SYPHILIS.—Lang believes that at the time of the infection with syphilis a cell infiltration takes place which forms a wall of isolation between the diseased centre and the sound parts in the neighborhood. A part of the syphilitic poison is thus rendered harmless, while the rest gains access into the system either by means of the lymph-cells into the lymphatics, or directly into the blood-vessels. If by the former way, the syphilitic infection will take place gradually; if by the latter, at once. Another way of infection is by what he calls regionary infection, by which is meant that the poison is carried into the regions in the neighborhood of the original focus through the interstices of the tissues, and there gives occasion to the formation of papules. The frequent infection of the rectum in women is, in most cases, due to the regionary infection from the primarily infected genitals. Another manner of the spreading of syphilis is the "post-initial infection," in which, on a region distant from the initial lesion, another initial manifestation appears, as on the lip from a genital chancre. An initial lesion with intact epithelium can only spread by way of the lymph-channels and tissue-spaces, while an ulcerated initial lesion permits all possible ways of infection. A part of the syphilitic contagion will be destroyed in the blood, a part got rid of by the excretory organs, and the rest can give rise to irritative processes, while some may remain for years quiescent, then to give rise to gummatous formations. During these years the poison must have undergone important modifications, as it is not infectious in the gummatous stage. The poison sometimes remains fixed in a certain organ without impairing the functions of the organ.—*The New York Medical Journal.*

PHYSICIANS IN THE CIVIL SERVICE.—The Government offices at Washington are fairly overflooded with retired M.D.'s, most of whom are working for a mere song, whose melody, however, is more voluminous than the clink of the scattering dollars that were wont to jingle into their coffers while they were still practising physicians. The young doctor assuredly traverses a hard road, but there are prizes to be won by him who pegs it out to the end.—*Philadelphia Record.*

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 20, 1889.

## A PHYSICIAN'S STUDY OF POVERTY AND ITS CAUSES.

No class of men come into such close and constant relations with the poor as physicians. It might be expected that they should be able to contribute something of value to the subject of poverty, and its social causes. This, in fact, physicians have done. In the June number of *The Forum*, Dr. H. D. Chapin has contributed an interesting and suggestive article on the subject. We doubt not that students of sociology will find in it more of immediate practical value than in learned treatises on single-tax or co-operative commonwealths. Our world-betterers have two duties before them, one to remove immediate distress and its causes as far as possible, the other to encourage the adoption of some social system which shall eliminate as far as possible poverty and misery. The prophets of new dispensations have their uses, but we confess to a greater liking for those who are content to help their fellow-man as much as they can now, without waiting for society to be reorganized on some new basis.

In the article referred to, Dr. Chapin states that, while one of the gravest problems to-day confronting society is found in the wide extension of great poverty, very few, unfortunately, of the panaceas offered to remedy this state of affairs are based upon a correct appreciation and knowledge of the operation of natural law. A careful study of this subject is desirable, inasmuch as poverty tends to be especially dangerous to social order under democratic institutions. With more freedom come greater wants, and a greater sensitiveness to social disadvantages. The presence and growth of extreme poverty and a sharp struggle for subsistence, particularly in our large cities, force themselves upon the attention of physicians who serve in the hospitals and dispensaries erected for the poor. After some years of such service, the author has come to the conclusion that physiology can afford the best preliminary solution of some of the problems of sociology. That there is some defect in our method of dealing with the poor is shown by the fact that, in spite of the large sums annually donated for such purposes and the good thereby accomplished, the real problem of grinding poverty does not seem to have been touched. As a result of a little more than five years' work, the Charity Organization Society of New York reports 101,916 families who have sought or received relief, which is equivalent to 407,664 persons living in actual or simulated dependence. An investigation of this vast army of unfortunates will, in very many cases, show a combination of ignorance, inefficiency, and shiftlessness which are largely the results of physical and mental ill-health. This being the case, public opinion must be directed more and more toward the means of increasing and preserving physical, mental, and moral health and vigor among the poor and unfortunate. Much disability comes from an utter ignorance of the simplest hygienic laws. This is, perhaps, most notably seen in regard to food. Granting the lack of means to purchase a variety of food, that form of nourishment should be selected which will yield the most energy, and which can be easily digested. This is precisely what is not done. The most glaring instance of this is seen in the diet of the very young, at a time when growth is extremely active. Such errors cannot be excused on the ground of extreme poverty, as the cost of proper nutriment—milk in some form—is less than that of the food so often substituted. The resultant rickets, with its softening of the bones and various developmental changes, may seriously handicap future healthy growth.

At his children's clinic, Dr. Chapin found, out of one hundred cases presented for treatment, forty-three showed marked evidences of this taint, in addition to the illness for which medical aid was sought. All efforts to relieve the very poor must start and end in the family, which constitutes the fundamental unit and basis of society and the State. No institution can take the place of the family. The domicile must hence assume great importance, not only as regards the efficiency, but also the morals, of its occupants. The problem of housing the poor is not so easy of solution as it looks. Reduced to a simple form, it would seem as if the destruction of bad tenements and the construction of good ones would settle the question. Unfortunately, a change of domicile will not necessarily change the nature of the inhabitants. In order to have a clearer conception of the condition of the very poor in tenement-houses, and the mutually acting relations of the people and their environment, it is necessary to go back and study their previous condition before coming to this country, as most of them are foreigners or of foreign descent. In the Irish census of 1841, touching the social condition of the people, the astonishing discovery is made that about seventy-seven per cent. of the people lived in cabins without floors, chimneys, or windows. These data are specially pertinent, as in the decade following 1847, 944,798 Irish immigrants landed in New York. Many of the Italian and other immigrants now swarming into New York find in the poor tenements better quarters than they are accustomed to. From this aspect it would seem as if the tenement-house system of our large cities were an upward step in evolution so far as many foreigners are concerned, quite as much as an accidental and unfortunate result of crowding on a restricted area. The plan advised by Dr. Chapin is to educate the poor—to elevate them in their own sphere, before trying to take them into a higher one that they cannot fill. Such education can only be accomplished by visiting the poor, and can be better done by women than by men. If intelligent help is to be extended, it must follow an investigation of the circumstances and character of those needing it. Something more than money must be taken to the poor and helpless. We must bring to them knowledge, foresight, a better judgment, a

stronger will, and to a certain extent must exercise these qualities for them, until they begin to give evidence in some degree of possessing them. The only kind of help that does good and not harm is that which leads to self-help. This relief will be slow, as it involves undoing habits of life formed by years of unfortunate environment. Dr. Chapin maintains that the physician, who has so much to do with the sick and ailing, can often have an insight into social problems that is denied to political economists.

## THE ELIXIR OF YOUTH.

It is curious, in this age of scepticism and of scientific reasoning, to read in our Paris letter of the discovery of the elixir of youth, and to learn that the one who claims to have found this longed-for potion is no less a person than the president of the Biological Society of Paris. Yet, at a recent meeting of this society, M. Brown-Séquard gravely asserted that he had extracted a liquid from the testes of animals, which, when injected into other animals or man, rejuvenated them and removed the infirmities of age.

The first experiments were made upon dogs. An old dog, who had long since abandoned the company of the fair sex, was subjected to a series of these injections, with the result that no puppy just gaining consciousness of the powers of ripe doghood was more ready to test those powers than was this quondam decrepit specimen of caninity. Encouraged by such promising results of his experiment, M. Brown-Séquard determined to try the effects of the injections in his own person. The results surpassed his most sanguine expectations. Things that he had been unable to do, or to do but feebly, for many years past, he was now able to execute to his entire satisfaction. He was formerly constipated, by reason of a paretic condition of the large intestine, but now his bowels were as those of "a romping boy." Formerly urination was feeble and the stream of water was propelled with but little force, owing to vesical weakness, but now Gargantua himself would envy the vigor of his performance of this act. Formerly he was obliged to rest from all intellectual effort after dinner, but now his thoughts flowed as freely after dinner as before breakfast. He could now stand on his feet for three hours at a time without feeling the least fatigue. There were other functions also, of which he did not care to speak more particularly, which had been re-established in all their pristine vigor. In short, he felt himself to be at least thirty years younger, and all this as a result of fifteen injections of testicular juice—at the rate, therefore, of two years for each injection. It is fortunate that the experiment was not continued further, for fifteen or twenty more injections, at the same ratio of rejuvenation, might have worked a startling change in the venerable scientist.

The improvement was not merely a temporary one, due possibly to a slight stimulation by the injections, as two weeks had passed at the time of his report, and he had lost none of his thirty years during that period.

Brilliant and epoch-making as this discovery is, we cannot but regard it as incomplete, for the male sex alone can profit by it. A sad condition would result were all the old men rejuvenated, while their aged companions through life were still weighed down by the heavy hand of time. Indeed, Dr. Brown-Séquard himself, with his increased mental acuity, was not slow to note the one-sidedness of his discovery. He suggested that the injection of ovarian juice might render the same service to the aged of the other sex, and he called for volunteers among the female doctors of advanced years to submit themselves to the experiment. Let us hope that the response to his call will be prompt, and that many of the old ladies of the profession in Paris will be willing to become young again for the sake of the science which they love so well.

## DEATH BY ELECTRICITY.

As our readers know, we have not been very ardent advocates of the law providing for the execution of criminals by electricity. It has seemed to us that, apart from the question of obtaining currents that would kill *cito et jucunde*, the methods proposed involved cumbersome paraphernalia, and might disfigure and convulse the victim.

The attempts of the counsel for the condemned man Kemmler, however, to show that electricity is not a suitable agent for capital punishment have brought out exhibitions of electrical non-expertness almost sufficient to cause a revulsion of feeling toward the new law. There can be no doubt whatever that electricity can kill, and kill certainly and uniformly, nor is there any doubt that apparatus can be so adjusted as to kill a man, with as much certainty at least as there is in any human affairs.

The question is really and solely one of æsthetics. The lethal current may possibly burn or scald; it may convulse, producing unpleasant contortions; and the machinery for its application, with all its tables, straps, adjustment of wet electrodes, etc., is more complicated than hanging.

## THE REGULATION OF PRELIMINARY MEDICAL EDUCATION.

All interested in the progress of medical education and the elevation of the status of American medical students will learn with pleasure that the New York State Legislature recently enacted a law requiring of medical students a certain standard of preliminary education.

The law reads as follows:

"Section 1. Before the Regents of the University of the State of New York, or the trustees of any medical school or college, within this State, shall confer the degree of doctor of medicine on any person who has not received a baccalaureate degree in course from a college or university duly authorized to confer the same, they shall require him to file with the secretary or recording officer of their university or college a certificate showing that, prior to entering upon the prescribed three years' study of medicine, he passed an examination conducted under the authority and in accordance with the rules of the Regents of the University of the State of New York, in arithmetic, grammar, geography, orthography, American history, English composition, and the elements of natural philosophy, and such certificate shall be signed by the secretary of the regents and countersigned by the principal or commissioner conducting said examination.

"Section 2. This act shall not apply to persons who have already entered upon the prescribed three years' study of medicine, nor shall it alter the time of study or the courses of medical instruction required to be pursued in the medical colleges of this State by existing statutes.

"SECTION 3. This act shall take effect immediately."

This law, which, it must be confessed, is somewhat paternal in its scope, places the students of medicine on the same footing with the students of law, who, before they enter its study, must also pass a regents' examination.

It should be distinctly understood that the law does not apply to students who have already matriculated; but all persons hereafter intending to get medical degrees in the medical colleges of this State must pass a preliminary examination. The Chancellor states that medical students may enter the examinations already held three times every year at each of the three hundred and eight academies and high schools of the State under visitation of the regents; and, in addition to this, provision will be made for special free examinations for medical students, as is now done for law students.

The Chancellor sends to the faculties of the different schools the following queries:

"1. To what extent, if any, should the grade of the examinations be lowered from the standard at present used in our academies?

"2. Would you favor a law compelling graduates from medical colleges outside of this State to comply with the above provisions as to preliminary education before practising in this State?

"3. At what times and places and how many examinations a year would you recommend?

"4. How would you regard an amendment to the law allowing the regents' examination to be taken during the first of the prescribed three years' study of medicine, instead of 'prior to entering' on such study?"

We venture to say that the profession of the State, as well as the faculties, will be decidedly averse to lowering the requirements. They should eventually be made much more stringent.

It certainly would be unfair to graduates of our State institutions to compel them to have special qualifications, when graduates from just over the border do not have to possess them. Unless some provision is made the medical students will slip off to some neighboring State college, get their degree, and return. We trust that there may be found some practicable way of amending the law in this direction. As to the fourth question, it will be quite imperative that the preliminary examination be allowed, if necessary, after probative matriculation. It would be difficult to accommodate the many students from outside the State otherwise. Furthermore, some provision ought to be made by which certificates of examinations from high schools and academies outside the State may be made equivalent to regents' examinations.

---

### REGULATION OF VETERINARY PRACTICE.

WE are glad to learn that the Legislature of Pennsylvania has enacted a law regulating the practice of veterinary medicine and surgery. The law provides, "That every person who shall assume, or use, or cause to be used, any title pertaining to the practice of veterinary medicine or surgery, or any of the branches of veterinary medicine or surgery, shall be a graduate of a legally chartered veterinary college or university, having the power or authority to confer the degree of veterinary surgeon or analogous title, except as provided for in section two; and such practitioner shall be required to register in the book kept for that purpose in the office of the county clerk of the county in which he resides."

It is stated in the *Journal of Comparative Medicine and Surgery* that the Legislatures of New Jersey and California have bills of similar purpose before them. There is much in comparative pathology and in the hygiene of the domestic animals that is closely related to the practice of human medicine, and the advancement of veterinary science will be a help to medical science as a whole. We trust that the regulation of veterinary practice may be undertaken by all the States.

---

## News of the Week.

BROWN-SÉQUARD'S NEW REJUVENATOR. — Brown-Séquard's statements regarding the stimulating power of testicular juice, which were received with much incredulity, have been in a measure confirmed through further experiments by M. Variot, who made a communication to the Société de Biologie on June 29th. The patients chosen were debilitated men, aged fifty-four, fifty-six, and sixty-eight years respectively, and they were not informed of the nature of the treatment adopted. In all three cases the injections were followed by general nervous excitement, increased muscular power, and stimulation and regulation of digestion.

Brown-Séquard is not the first to lay stress on the potency of juices artificially extracted from the generative organs. Horace, says *The Medical Press*, in one of his odes, beseeches the witch Canidia to reveal to him the secret of the draught which she prepared at night by crushing in a mortar pieces of flesh torn from the most fiery horses of Rome, and the patricians, says the Latin poet, used this mysterious liquid with great confidence. Consequently M. Séquard is but an humble successor of Canidia! It would not be at all surprising if the testicles contained some stimulating leucomaine. We know that the salivary glands can generate a poison, and Dr. Wooldridge found an active principle in the thymus gland which caused a rapid clotting of the blood when injected into the veins. The toxic agents in the urine secreted at night are said to be stimulating and anti-hypnotic. There is not much known about the leucomaines, and possibly Brown-Séquard has hit upon one of them. That his discovery, if it is one, is more than the discovery of some stimulating product of tissue change, we do not believe. But it will no doubt give a great impulse to the consumption of lamb fries.

THE NAPHTHA HABIT.—The *Medical Standard* calls attention to the growth of the "naphtha habit" among the female employees of rubber factories. The inhalation of naphtha fumes produces a peculiarly agreeable inebriation. Naphtha is used to clean rubbers, and is kept in large boilers to the valve of which the female employees obtain access and breathe the fumes. The habit was introduced from Germany, and is chiefly found in the New England States.

MCGILL UNIVERSITY.—Dr. George Ross has been appointed Professor of the Practice of Medicine, and Dr. Richard Z. McDonnell Professor of Clinical Medicine, in the Medical Faculty of the University.

SELLING CIGARETTES TO CHILDREN.—A conviction, under the new law in New York State prohibiting the selling of cigarettes to children under sixteen years of age, has been obtained. The offender was compelled to pay a fine of fifty dollars.—*Medical News.*

THE ORGANIZATION OF THE TENTH INTERNATIONAL MEDICAL CONGRESS, which is to be held at Berlin, August 4 to 9, 1890, is under way. At the call of Professors Virchow, Bergmann, and Waldeyer, a large number of representative men will meet at Heidelberg to begin the arrangements.

FADGES FOR PARISIAN STUDENTS.—The Parisian students have recently decided to wear certain marks of distinction, to denote the courses which they are pursuing. Medical students will wear, on a boutonnière of red and black, a little violet band with a skull made of some white metal. Army medical students will wear, on a garnet boutonnière, the symbol of health—the rod of Æsculapius in gold. Students of pharmacy will be distinguished by the emblem of pharmacy, a silver shaft encircled by a gold serpent, worn on a green boutonnière.—*New York Medical Journal.*

THE HOSPITAL OF JOHNS HOPKINS UNIVERSITY.—Dr. Henry M. Hurd, of Pontiac, Mich., has been appointed superintendent of the hospital. He is at present the superintendent of the State Asylum for the Insane, at Pontiac.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION will meet at Evansville, Ind., September 24, 25, and 26, 1889.

GOING TO CHURCH.—This is what a Dakota doctor advises about it: "I went to church and Sunday-school, and if any of you young M.D.'s do not attend Sunday-school, you should begin, as it will help you to a good class of patients, besides its grave duty as a gentleman and a man of education. I have a class of young misses, and am sure they help me to as many patients as any of my friends; besides, you had better be at church than hanging around the streets or saloons."

DEATH OF DR. J. LEWIS SMITH, JR.—We regret to learn of the recent sudden death of Dr. J. Lewis Smith, Jr., of this city, a very promising young physician.

A HOSPITAL FOR ANN ARBOR.—The city of Ann Arbor, Mich., has voted to issue bonds for $25,000 for the erection of a hospital, for which the legislature appropriated $50,000.

THE LAW REGULATING THE PRACTICE OF MEDICINE IN MAINE has been declared invalid through a technicality.

DR. HARRIS H. BEECHER, late Assistant Surgeon of the One Hundred and Fourteenth New York Volunteers, and a well-known writer and speaker of the Shenango Valley, died at Norwich, N. Y., on July 15th, aged sixty-nine years.

DEATH OF JOE FOGARTY.—Almost every physician in this city, and hundreds living elsewhere, knew of Joe Fogarty who, for nearly twenty years, was assistant keeper of the Morgue, and who died somewhat suddenly last week. Fogarty had a talent for the peculiar and repulsive kind of work in which he was engaged; and he pursued it without becoming brutalized, or losing the natural kindliness of his disposition.

VERMONT UNIVERSITY MEDICAL COLLEGE.—The annual commencement of the medical department of the University of Vermont occurred, July 15th. There were sixty graduates. The annual address was delived by ex-Minister E. J. Phelps, who spoke on "The True Standard of Success in Life."

DR. AUSTIN WHITE THOMPSON, for some time Assistant Superintendent of the Northampton (Mass.) Asylum for the Insane, and for fifteen years proprietor of the Shady Lawn Retreat, died last week of consumption. He was born at Pelham, May 22, 1834. He was graduated at Harvard in 1854 with salutatory honors. After special study at various hospitals, he was appointed Assistant Superintendent of the Northampton Hospital by Dr. Earle. He was forced to retire on account of poor health at the end of two years. In 1874 he started the Shady Lawn Retreat. Dr. Thompson was a man of literary tastes and a poetical turn of mind. He was also a skilful surgeon.

CONTINENCE AND SYPHILIS.—*The Lancet*, commenting editorially upon our remarks regarding continence as a preventive of syphilis, adds: "'Though Dr. Gowers' testimony to the importance of chastity as a means of health is the last great note sounded to Englishmen, it does not stand alone in medical literature. There is another voice which may be recalled here which will sound for generations yet, as characteristic in its ethical strength as in its medical and scientific authority. Sir James Paget, in his clinical lectures, speaking of patients that expect us to prescribe fornication, says: 'I would just as soon prescribe theft or lying, or anything else that God has forbidden. If men will practise fornication or uncleanness, it must be of their own choice and on their sole responsibility. . . . Chastity does no harm to mind or body; its discipline is excellent; marriage can be waited for; and among the many nervous and hypochondriacal patients who have talked to me about fornication, I have never heard one say he was better or happier after it; several have said they were worse; and many, having failed, have been made much worse.'"

HEART-FAILURE AS A CAUSE OF DEATH.—"It would be an excellent idea," says the *Manchester Union*, "if physicians of the present day would invent some other reason for about all of the deaths which occur nowadays than the cheap fraud, 'heart-failure.' This might not be of serious moment were it not for the fact that hundreds of people are being nearly frightened to death by the constant use of the cause for sudden deaths, and many people who are sick, and necessarily have some heart symptoms, are kept in constant terror by reading or hearing in other ways of death after death by heart-failure. There are probably no more deaths from heart-failure in these times than heretofore, but a new cause for death has been coined, and the nervous and timid are being severely injured by it." We would suggest that hereafter physicians use the term "cardiac asthenia," which has a learned sound and means just the same. The immediate cause of death in many diseases being, in fact, "heart-failure," we do not see how otherwise the "nervous and timid" can be protected.

DR. A. E. M. POND, the inventor of Pond's sphygmo graph, died at Rutland, Vt., recently.

# Society Reports.

## ONTARIO MEDICAL ASSOCIATION.

*Ninth Annual Meeting, held at Toronto, Canada, June 15 and 16, 1889.*

(Reported by our Canadian Correspondent.)

DR. W. H. HENDERSON, OF KINGSTON, PRESIDENT, IN THE CHAIR.

MEETING opened with an attendance of two hundred and seventeen members.

After the report of Committee on Arrangements had been presented, DR. W. J. GIBSON, of Belleville, read the history of a case of

SYMMETRICAL GANGRENE,

which he was inclined to consider an example of Raynaud's disease. The gangrene was limited to the toes, the patient (a male, aged forty-one) eventually losing all the toes of the right foot and the second and third toes of the left foot. The constitutional symptoms were less severe than the local. The onset of the disease was sudden, commencing with pain and a feeling of numbness in both arms and legs; a condition of ischæmia was then observed in the feet; this was followed by cyanosis, erythema, and gangrene, limited to the parts above mentioned. Dr. Gibson concluded his paper by giving a short sketch of the supposed pathology of Raynaud's disease, and also a brief account of its clinical history.

DR. J. CAMPBELL read a paper giving reports of cases in practice, one of which was an interesting case of

LOBULAR PNEUMONIA IN A PRIMIPARA AT CONFINEMENT.

This case was marked by a high temperature and complete suppression of lacteal secretion, and ended in recovery of the patient.

DR. R. W. BRUCE SMITH, of Seaforth, read a paper entitled

REFLEX NERVOUS PHENOMENA, DUE TO PREPUTIAL CONTRACTIONS.

He briefly related a few cases, coming under his own observation, of nervous irritability in children, arising as a result of narrow prepuce, accompanied by preputial adhesions.

CASE I.—A male child, aged five months. Parents complained that the child cries almost constantly without any apparent cause, is very fretful, and has marked evidence of nervous prostration, trembling of eyelids, convulsive movements of the limbs, etc. On examination Dr. Smith found a pinhole orifice, with extensive adhesions, between the prepuce and glans. He broke down the adhesions, and forcibly dilated the prepuce, so that it could be drawn back over the corona glandis; the parts were then thoroughly cleansed. As a result of this small operation the patient was relieved of all nervous symptoms.

CASE II.—A male child, aged eight months. This child was very fretful, especially during micturition. These symptoms of fretfulness and dysuria had existed for three months. Dr. Smith treated this case by means of gradual dilatation, until the prepuce could easily be retracted over the corona. The result was entirely satisfactory, there being no return of the symptoms.

CASE III.—A male child, who at eighteen months showed no inclination to walk. About this time had several convulsions; at the age of three years could scarcely stand; legs were very weak, but not wasted. On general tonic treatment made no improvement. On examination an elongated prepuce was found bound down to the glans. When the adhesions were broken down and the prepuce dilated, the latter could be easily retracted. The parts were then thoroughly cleansed and the smegma, as in each of the other cases, was removed. In about a fortnight there was marked evidence of improvement, and from this the child progressed rapidly, so that at the end of four months he was able to run about with the other children.

In concluding his interesting paper Dr. Smith alluded to Mr. Edmund Owen's teaching, that a small preputial or urethral orifice and adherent prepuce were, perhaps, the commonest causes of hernia in children. He also briefly referred to Mr. Bryant's statistics bearing on the same point, and urged attention to a subject upon which textbooks say so little. He believed that in some cases with marked nervous symptoms in male children we may find a causative relation to those symptoms in an abnormal condition of the penis, and that by directing our attention to the relief of that condition we may convert a feeble, puny, wakeful, and irritable boy into a healthful and happy child.

DR. NEWMAN, of New York, made a few remarks, highly approving of Dr. Smith's treatment and method of operating, deprecating circumcision in those cases where dilatation is quite sufficient. Drs. McGuire, of Guelph, Murray, of Thorndale, and others continued the discussion.

---

AFTERNOON SESSION.

THE PRESIDENT cordially welcomed the fraternal delegates present from American Medical Associations, and invited the following visitors to the platform: Dr. Alex. J. C. Skene, of Brooklyn; Drs. Roswell Park and Tremaine, of Buffalo; Dr. Newman, of New York; Dr. Foster, of Portland, Me., and others.

DR. W. H. HENDERSON, of Kingston, then delivered the

PRESIDENT'S ADDRESS.

He first expressed his gratitude for, and appreciation of, the high honor paid to him, as one of the younger members of the Canadian medical profession, in being elected to the office of president of this most prosperous association. Appropriate "in memoriam" reference was then made to the late Dr. R. P. Howard, of McGill College, and others who had been called away during the year. Referring to the present condition of the medical profession in the Province, the President uttered some apt and interesting remarks concerning the wide and rapid diffusion of knowledge at the present time. He thought that "at no time in the history of our country has the medical profession of Ontario been in a more favorable state than at the present time." Congratulatory and complimentary remarks regarding the high standard of professional education in the Province, and the increase of hospital accommodation were indulged in, and reference was made to the enterprise shown by Canadian students in acquiring hospital experience of the most valuable kind in Europe and the United States. The President then directed his remarks to a review of the medical legislation at present existing, and expressed regret that the Ontario Medical Council, an institution which has done much to elevate the standard of medical education in the past, should persist in enforcing the rule excluding men who possess British diplomas from practising in this Province. He did not consider it just that an M.D. from London University, or a Fellow or Member of the Colleges of Physicians or Surgeons should, on coming out to this country, be required to undergo a further test of his ability, at a very considerable expense, before he shall be allowed to practise in Ontario. He also believed that the fact of a British diploma exempting a man from passing the Ontario Medical Council had, in the past, been an incentive to Canadian students to visit the hospitals and compete in the examination halls of Great Britain. This was particularly of value to those who felt they could not afford to pay the high fees charged for both examinations. He expressed the hope that our medical legislators would see their way clear to remove this obstacle to the medical student, and which might ulti-

mately, by discouraging post-graduate study abroad, impair the future usefulness of the profession. To those who would place obstacles in the pathway of our students, and who, though perhaps unintentionally, prevent them from pursuing their post-graduate studies abroad, he would, he said, answer in the words of Medea to the Corinthians, viz. :

> There are who distant from their native soil,
> Still for their own and country's glory toil;
> While some, fast rooted to their parent-spot,
> In life are useless and in death forgot.

He alluded then with expressions of regret to the action of certain medical men who, notwithstanding the unexcelled system of medical education in this Province, carry on their practice with unblushing quackery. The fact that they had regularly obtained registration at the Medical Council was set up as a defence, but permission should be given by Parliament to the Medical Council to cancel the diploma of any person acting in an irregular manner. Then this question could be speedily disposed of by the council, and, while the public would be better protected, our profession would be freed from the few of whom we are ashamed, and from whom we would be gladly separated. Dr. Henderson then eloquently made reference to the importance of making more provision for post graduate study and pathological research. He urged the claims of the profession for government aid in founding and establishing a great "Provincial Medical Exchange," where every practitioner of medicine in the Province might bring the results of his labors, and where facilities for pathological study might be afforded to stimulate research and original investigation among all members of the medical profession. While not advocating the expenditure of public money for medical education in the ordinary routine of college work, he hoped that in the near future our provincial authorities, regarding as they do education as the corner-stone of our civilization, will decide to encourage the post-graduate study of medicine by liberally providing for our higher educational needs in that respect. The investment would, he considered, be a profitable one from every stand-point.

The address, which was a most able and eloquent presentation of the present needs of scientific medicine in Ontario, concluded with a graphic reference to the achievements which might yet be made in the interests of the profession in Canada, and earnestly urged co-operation in maintaining untarnished the high reputation already attained, and by patient, diligent advancement adding fresh lustre to the honors achieved in the past.

### DISCUSSION ON SURGERY.

Dr. W. T. Aikins, of Toronto, opened the discussion on surgery with the subject,

### THE GENERAL MANAGEMENT OF THE PATIENT AND SICK-ROOM IN SURGICAL CASES.

He first dealt with the question of pure air in the sick-room, and maintained that sufficient attention was not paid to what some might consider the minor details in the arrangement of the sick-room. He instanced the large mortality in Canada every year from phthisis as evidence of the fact that too little attention was paid to the proper ventilation of our homes and schools, and, above all, to the sleeping apartments. Why was it regarded of such importance to guard carefully the proper disposal of fæces, while at the same time little was done to warn people of breathing over and over again the same air? If, then, ventilation was of so much importance to those in health, how much more detrimental would it be to neglect looking after the purity of the air-supply to those who have undergone the shock of some operation, or might be debilitated by some exhausting discharges. He urged the importance of every surgeon taking the precaution to see that there was a means of escape for foul air near the roof or ceiling of every room where a patient was confined. A practical lesson was given in the filtering of air. The placing in the window of the sick-room of two sheets of mosquito-netting, with a thin layer of cotton-batting between these, was recommended by Dr. Aikins. He related several examples where attention to these details had proved advantageous.

Dr. Ruttan, of Napanee, continued the discussion, and said he had used the window netting with great satisfaction. His plan was to place between the layers of the netting antiseptic cotton or oakum, to which some reliable antiseptic agent had been added. His method in private practice was to have the room for the operation carefully cleaned with a bichloride solution the day before, and to have the antiseptic filter in the window several hours before the operation was commenced.

Dr. Britton, of Toronto, considered it was very important to see that the patient had none but the most cheerful surroundings. He thought there had been too great a tendency, of late years, to restrict the diet of invalids, and believed that the mortality in lying-in cases was increased thereby. He briefly showed the advantages gained by having small wards in hospitals, and of the cottage system, in order to secure what was of the greatest importance, viz., a regular supply of fresh air to the convalescing patient.

Dr. Skene, of Brooklyn, N. Y., thought foul air was even worse for a patient than foul water. We must, he said, all breathe air, but he did not think, from the appearance of the robust Canadians he had before him, that many of them drank only water. In abdominal surgery he was particular to have the air of the operating-room as pure as possible. He was careful to limit the number of spectators in the operating-room, for he had noticed that while some surgeons made elaborate preparations in regard to the room, bedding, instruments, etc., they were not careful in keeping the air free from being contaminated by the exhalations of numerous spectators. He favored the method of filtering the air as advocated by Dr. Aikins, and instanced several institutions where he had seen the same used with satisfaction.

Dr. William Oldright, of Toronto, considered that it was important to have the temperature of the room always suitable and uniform, and, while the air must be kept as pure as possible, its temperature should be carefully looked after.

Dr. Roswell Park, of Buffalo, N. Y., then read, by invitation, a paper on

### THE RADICAL CURE OF HERNIA.

He first briefly reviewed the many operations which had been devised with the hope of a permanent cure, and then minutely described his method of operating, which, he said, could not be regarded as either new or original, but was rather a combination of several well-known plans. After shaving the parts and thoroughly washing them antiseptically, he made an incision over the external ring. The sac will usually be found without much search, but is sometimes blended with the cord in such a way as to be very confusing to the operator. When the sac is isolated, after splitting up the canal if necessary, it is opened. If omentum is found it is ligated and removed, the pedicle being dropped. The sac is then ligated with catgut close to the external ring, and divided close to the ligature. If the hernia be a congenital one, it is similarly ligated close to the testicle, so as to leave a tunica vaginalis. A similar procedure is adopted in femoral hernia. The pillars of the ring are then drawn close by silver wire, which is twisted, cut short, and the ends turned over upon themselves. The integumentary wound is closed with catgut, generally without drainage. If asepsis be perfect, union should be obtained in forty-eight hours. In femoral hernia he generally adopted Ball's plan of twisting the pedicle of the sac. He does not often wire the femoral ring, but leaves it to fill by granulation. In umbilical hernia, usually found in women with lax and flabby abdominal walls, he favored extirpation of the sac and hinging the margins of the ring together in two or three tiers. The truss he did not consider should be worn after the opera-

tion, as its pressure had a tendency to cause absorption of the granulation-tissue. He had operated in cases of acute strangulation twenty times, in patients ranging from six to seventy-eight years. Of these, four died, and one had a relapse. He had fifty two cases of deliberate operation for radical cure, and all recovered without any sign of disturbance. Of these, fifteen were in females; six of these being umbilical and two femoral. He did not hesitate to operate on both sides simultaneously, and had in some cases relied solely upon cocaine as the anæsthetic.

Dr. McFarlane, of Toronto, had operated three times with good results, from Wood's operation with silver wire, and after two years there had been no relapse. He had also had two successful cases in which he operated according to Czerny's method. His experience, however, taught him, if a suitable truss, properly adjusted, will keep the bowel reduced, it is preferable to any operation.

The Association then divided into Sections.

---

## SURGICAL SECTION.

The President nominated Dr. Howitt, of Guelph, Chairman of this Section.

Dr. Mitchell, of Enniskillen, presented a paper on

### EARLY OPERATION IN CASES OF OBSCURE ABDOMINAL DISEASE,

in which he made reference to the frequency with which the general practitioner, in country practice, meets with urgent cases in which an abdominal section is called for. He related two cases, where after some delay, owing to the refusal of the patient's friends to consent to an operation, he had opened the abdomen, in both cases to relieve obstructions, caused in the one case by hernia, and in the other by a large abscess pressing upon the sigmoid flexure. In the case of hernia the patient rallied, passed flatus on the following, and fæces on the fourth, day. She, however, died on the fifth day. In the second case, after evacuating the abscess the bowels moved and the patient improved for some days after the operation, but ultimately died from exhaustion. Dr. Mitchell considered that both of these cases might have been saved if an early operation could have been done.

Dr. Mann, of Buffalo, thought that not only should we operate earlier, but that more cases should be operated upon. He related a brief history of a case of pyo-salpinx of six years' standing, and also another of abscess of the ovary, as evidence in support of early operative procedure. There was difficulty in diagnosing pyo-salpinx, owing to the fact that there was often little or no rise of temperature, and sometimes nothing else, to direct suspicion to the presence of pus. The only guide to diagnosis in such cases seemed to be the previous history of repeated attacks of so-called pelvic cellulitis. He related a case of laparotomy, performed successfully for general septic peritonitis following labor, in which one pint of pus was evacuated and the patient had made a good recovery.

Dr. W. Oldright, of Toronto, spoke of a case he recently had of hæmato-salpinx, in which he had operated with a good result. There had been in this case a history of chills, high temperature, and sweating, and a diagnosis of pelvic abscess had been given.

Dr. Groves, of Fergus, was in favor of evacuating pelvic abscess in the female through the vagina. It was certainly the shortest way to reach the pus, and afforded the best facilities for drainage.

The discussion on ophthalmology was introduced by Dr. Moore, of Brockville, who had chosen for a subject

### GLAUCOMA,

one of the most important, he said, and dangerous diseases of the eye, which came frequently under the observation of the general practitioner; and it was of the utmost importance that an early and correct diagnosis should be made. Dr. Moore said he was convinced that the study of diseases of the eye, and especially clinical teaching of the subject, should have a more prominent place in the curriculum of medical colleges, for the general practitioner should be able to recognize and treat successfully all the ordinary diseases of the eye. Glaucoma was a disease so insidious in its course that it might destroy sight before the patient was aware of its presence. The points in diagnosis to be relied upon were: (1) Increased tension of the eyeball; (2) limitation of the field of vision, especially on the nasal side; (3) the hypermetropia; and (4) the anæsthesia of the cornea. We generally find acute inflammatory glaucoma preceded by a premonitory stage, the signs of which were often mistaken for neuralgia or stomach derangement. The nature of secondary and hemorrhagic glaucoma was referred to, and the treatment was then discussed. The operation of iridectomy was frequently resorted to, but gave the best results in acute and subacute cases. He thought sclerotomy was better in cases of simple glaucoma, as it does not disfigure the eye to so great an extent. Eserine is a valuable drug for lessening the tension, but atropia was certainly contraindicated. Attention must be paid to the general health, and particularly to digestion, which was often seriously at fault in these cases.

Dr. Burnham, of Toronto, thought that primary glaucoma was of more interest to the general practitioner, as the secondary affection soon drives the patient to the specialist on account of the severe pain. Primary glaucoma should be considered as either acute or chronic. In the former the severe headache was such as to often divert attention from the eye, so that the patient might become quite blind before he is aware that there is anything the matter with the eye. Then, if not attended to early, it may become necessary to remove the eye. There was a difficulty also in recognizing the chronic form of the disease on account of its resemblance to cataract, in there being dimness of vision without pain, so that the patient might be told to wait for the development of the cataract, and in that way total loss of sight result.

Dr. Palmer, of Toronto, thought iridectomy was to be preferred to sclerotomy in most cases of glaucoma.

Dr. R. A. Reeve, of Toronto, said he considered secondary glaucoma of more importance to the general practitioner than the primary form of the disease, owing to the rarity of the latter. The development of glaucoma in children, following ulceration of the cornea, should be looked for. He considered that eserine, on account of its usefulness to relieve tension, was the sheet-anchor in treatment.

---

## MEDICAL SECTION.

Dr. W. B. Geikie, of Toronto, acted as Chairman.

Dr. McKinnon, of Guelph, presented a paper on

### VENESECTION IN PUERPERAL ECLAMPSIA.

His experience warranted him in warning young practitioners against placing confidence in bromide of potassium, chloral hydrate, or even hypodermic injections of morphia, in cases of puerperal eclampsia. The use of the lancet was no new treatment, but rather a return to old practice, for time had brought forth nothing he considered equal to it in those cases. He thought death usually resulted from pressure on the brain from serous effusion, hemorrhage, or œdematous infiltration, and to combat such there was nothing of such value as free venesection. He did not wish, he said, to be understood as recommending venesection as a measure to arrest the convulsion, but by diminishing the tension on the cerebral vessels to disarm the convulsion of its fatal power. When called to a case of puerperal convulsions he always adopted the following as a guide to his procedure:

1. Bleed the patient if convulsion be severe or followed by coma.

2. Control the convulsion with chloroform.

3. If the patient be at full time, take steps to terminate labor as quickly as possible.

4. Administer an active purgative—Epsom or Rochelle salts.

5. If the convulsions recur, give a large hypodermatic of morphia.

This interesting paper closed by giving an account of seven cases of puerperal eclampsia in which he had followed the above course of treatment with success in each case.

Dr. Richardson, of Toronto, looked upon venesection as the sheet-anchor in the treatment of puerperal eclampsia, for it not only prevents extravasation, but is the very best method for reducing the total quantity of poison in the system.

Dr. Holmes, of Chatham, would, besides employing venesection, use diaphoretics freely, and in markedly anæmic subjects would hesitate before bleeding.

Dr. A. H. Wright, of Toronto, contributed an excellent paper on

THE PREVENTION OF PUERPERAL SEPTICÆMIA.

He said he considered no apology was necessary for bringing such an ordinary subject before the meeting, for he maintained this matter should be continually discussed until sepsis became practically unknown in the lying-in room. It is anything but creditable to the medical profession that puerperal septicæmia is more common in private practice than in well-conducted hospitals? We are not to judge its effects simply from its death-rate, but must also take into account the amount of misery and suffering resulting from the milder forms of septicæmia. Can we prevent this septicæmia? Dr. Wright answered this question in the affirmative. How can it be done? By thorough and perfect cleanliness on the part of ourselves, and the essentials for such are hot water, soap, a nail-brush, and a penknife; on the part of our patients, proper clearing of bleeding surfaces and dressings which will keep them clean, and along with these good ventilation, thorough drainage, and perfect plumbing. Dr. Wright cautioned the profession against pinning their faith to any special antiseptic, thinking that, by simply using this, dirty hands and dirty instruments could be employed with impunity; at the same time he believed that modern antiseptic remedies furnish invaluable assistance in efforts toward asepticism. Dr. Wright then gave the following short account of the methods practised in the Burnside Lying-in Hospital, Toronto. On admission, the patient is bathed and dressed entirely in clothing belonging to the hospital. When labor comes on she is clothed in a clean night-dress and drawers. The presentation is made out by abdominal palpation. Vaginal examinations are made in the first stage, occasionally, but as seldom as possible. Each one who touches the patient first washes his hands thoroughly, using soap, nail-brush, and penknife, and then rinses them out in a solution of bichloride of mercury, 1 to 1,000. This process must be repeated before each examination. When the presenting part is pressing on the perineum the vulva is protected by a towel which has been soaked in the bichloride solution. After the delivery of the child no vaginal examinations are made; the placenta is expressed by the Dublin method. The assistant keeps the uterus contracted with gentle rubbing with the finger-tips. The soiled clothes are then removed, the nurse washing the vulva with a bichloride solution. No vaginal or intra-uterine douche is used either before or after delivery. The antiseptic pad is then applied. Dr. Wright then illustrated the making of this pad, which consists of absorbent cotton, enclosed in butter-cloth; before the dry pad is placed in position a layer of absorbent cotton wrung out of a bichloride solution is placed over the vulva, the pad lying on this. Septicæmia had been exceedingly rare in the Burnside during the last few years, the temperature rarely reaching 100° F.; the patients generally go out in two weeks after labor. Dr. Wright objected to vaginal and intra-uterine douches, "because they are unpleasant for the patients, because they interfere with the physiological rest which the torn and bruised parts should have, because septic matter or air may be introduced and brought in contact with rents in the cervix, vagina, or vulva, and finally because they are unnecessary." He also laid great stress on the danger of introducing the fingers into the vagina after labor; it is entirely uncalled for in the great majority of cases, the placenta being easily expressed by external manipulations; it is at this stage that septic matter is most readily taken up by the open vessels and the abraded surfaces. He believed that puerperal septicæmia is more frequently caused by absorption of septic matter by the torn fourchette or perineum than from any other source, therefore the practitioner should be careful to avoid this by the use of the antiseptic pads, and cleansing the vulva with the bichloride solution when the pads are changed.

Dr. Temple, of Toronto, agreed with the reader of the paper that there would be very few cases of puerperal septicæmia if the accoucheur took all necessary precautions. He also objected to the routine use of douches. In his own practice he never used an antiseptic pad, but simply a perfectly clean diaper. He believed that most septicæmic cases were due to absorption of septic matter by rents in the passages.

Dr. W. Gunn, of Clinton, then read a paper on

A CASE OF SCLERODERMA,

and exhibited the patient. He first gave a brief outline of the history, nature, and peculiarities of this rare form of skin disease, and then explained the history of the case presented. The patient, a male aged forty, upon whom the disease was well marked, was examined with much interest by members of the Section.

---

Evening Session.

The President first introduced Dr. Alexander J. C. Skene, of Brooklyn, N. Y., who was present by invitation, and read a paper on

INTRALIGAMENTOUS OVARIAN CYSTOMA.

This term, said Dr. Skene, embraces only those cysts which are developed from the ovary and situated completely within the folds of the broad ligament, being thus neither pedunculated nor provided with a sessile attachment, but surrounded by a capsule formed from both folds of the broad ligament. Two theories have been advanced to explain the origin and unusual position of these cysts. The first assumes that the ovary itself is placed between the folds of the broad ligament from developmental error. The second theory is that the cystoma burrows during its growth into the ligament. In order that this may come about it is necessary that the ovary, by a special formation, be closely attached to the ligament or fixed there by inflammatory adhesions. The latter view is supported by some observations in the author's cases. They are generally monocysts, a fact accounted for by Bland Sutton by their development from the deeper structures of the ovary—the paroöphoron. The position of the cysts with reference to the other organs is also of interest, because in different portions it would cause different displacements. Their anatomical relations were of the utmost importance in regard to their surgical treatment. As a point in diagnosis they are generally accompanied by more distressing pains in the pelvis, and more disturbance of the functions of the bladder and rectum, than are ovarian or parovarian cystomata. Physical examination shows that the cyst is fixed at its most dependent part, the fixation being at one side or extending from side to side, according as the tumor occupies one or both ligaments. Fluctuation is noticeable in the pelvic portion of the tumor. Dr. Skene then gave in detail the points of diagnosis from fibrocysts, etc. For treatment enucleation ranks first, as it

is applicable to more cases than any other method. The operation was fully described and drainage of the pouch advocated. The peritoneal surfaces of the edges of the pouch are brought together by a continuous catgut suture, and brought up and fastened to the peritoneal edge of the abdominal wound, if possible. Another method was to remove the cyst and capsule together by ligating the ligaments below the cyst by means of the repeated continuous ligature. Another was by a combination of these two methods. Unfortunately there are some cystomata of this variety which cannot be removed by any method known at the present time. These should be treated by drainage above, uniting the cyst to the abdominal wall, after removing as much of the cyst as possible. The drainage must be long continued and the recovery of the patient is generally tedious.

Dr. Mann, of Buffalo, and others took part in the discussion that followed.

The President then introduced to the Association the Hon. GEORGE W. ROSS, Minister of Education for the Province of Ontario, who made a few remarks welcoming the members of the profession to the city, and congratulating them on the interest shown by the large attendance in the welfare of the Association.

The discussion in medicine on the subject,

THE PROGNOSTIC SIGNIFICANCE OF MODERATE CARDIAC HYPERTROPHY AND DILATATION,

was then opened by Dr. Charles Sheard, of Toronto, and continued by Dr. McPhedran, of Toronto, and Dr. Bruce Smith, of Seaforth.

The Association then went into executive session, and considered certain amendments to the Code of Ethics.

---

SECOND DAY, THURSDAY, JUNE 16TH.

The meeting of the Association was resumed. After the transaction of routine business the meeting was again divided into Sections.

---

SURGICAL SECTION.

DR. E. E. KING, of Toronto, presented a paper on

THE USE OF THE CYSTOSCOPE IN DIAGNOSING OBSCURE BLADDER DISEASE.

This was followed by an interesting discussion, and the following papers: Dr. N. A. Powell, of Toronto, on "Demonstration of the Use of an Improved Form of Relaxation Suture;" Dr. J. E. White, of Toronto, on "Recent Modes of Treating Fractures above the Wrist-joint;" Dr. Newman, of New York, on "Electrolysis in Surgery and Gynecology;" Dr. Howitt, of Guelph, on "Miscellaneous Laparotomies;" Dr. Groves, of Fergus, on "A Case of Vaginal Hysterectomy, with Abdominal Ovariotomy;" Dr. Walker, of Toronto, on "Some Practical Points in Gynecology and Abdominal Surgery;" Dr. N. McPhatter, of Cleveland, O., on "Cholecystotomy." These papers were each followed by interesting discussions.

---

MEDICAL SECTION.

Papers were presented as follows: Dr. Price Brown, of Toronto, on "The Treatment of Phthisis Pulmonalis;" Dr. Smith, of Orangeville, on "Pathological Relations of Spleen and Bone Medulla;" Dr. Sweetnam, of Toronto, on "The Probable Future of Electricity in Gynecology;" Dr. Anglin, of Kingston, on "Cases of Typhoid Fever with Perforation of the Bowel;" Dr. McPhedran, of Toronto, on "Abortive Forms of Typhoid;" Dr. Ryerson, of Toronto, on "Some Forms of Headache;" Dr. Dickson, of Toronto, on "A Plea for Electricity in Medicine;" Dr. McKinnon, of Alvinston, on "Alcoholic Stimulants as Regards Quality."

GENERAL SESSION.

DR. ALLAN BAINES, of Toronto, opened an interesting discussion on obstetrics with the subject

LACERATION OF THE PERINEUM.

Drs. Barreck, of Toronto, Fenwick, of Kingston, A. H. Wright, of Toronto, and Howitt, of Guelph, followed in the discussion.

The evening session opened with the discussion in therapeutics, opened by Dr. Thorburn, of Toronto, on

THE USES AND ABUSES OF ANTIPYRETICS,

in which Drs. J. L. Davison and Wishart, of Toronto, took part.

After the reception and discussion of the reports of the various committees had taken place, the report of the Nominating Committee was presented, and by its unanimous adoption the following officers were elected:

*President*—Dr. J. Algernon Temple, Toronto; *Vice-Presidents*—1st, Dr. Lundy, Preston; 2d, Dr. Shaw, Hamilton; 3d, Dr. Fenwick, Kingston; 4th, Dr. Hanley, Waubaushene; *General Secretary*—Dr. D. J. Gibb Wishart, Toronto; *Assistant Secretary*—Dr. W. P. Casen, Toronto; *Treasurer*—Dr. E. J. Barreck, Toronto.

The report of the Treasurer showed an income for the year of $625. The newly elected president, Dr. Temple, of Toronto, was then conducted to the chair, and the Ninth Annual Meeting was brought to a close.

---

## KENTUCKY STATE MEDICAL SOCIETY.

*Thirty-fourth Annual Session, held at Richmond, Ky., May 8, 9 and 10, 1889.*

DR. L. S. MCMURTRY, OF DANVILLE, PRESIDENT, IN THE CHAIR.

THE attendance was good, and the meeting from the first promised to be an unusually good one. Reports of the Secretary, Treasurer, Committee on Arrangements, and other committees were briefly made. Ex-Governor James B. McCreary was present and made a speech, in which he extolled the medical profession very highly. He had served with them in the pursuits of peace and of war, in the legislative halls of the State and nation, had yielded his place in the gubernatorial chair to a doctor, and one of this profession, from his own city of Richmond, now occupied the office of Chief Justice of the United States.

On motion, it was voted to appoint a Committee of Reference in each county of the State to see to the

ENFORCEMENT OF THE NEW MEDICAL LAW,

by proceeding against all violators, and to use the money in the treasury of the Society for the prosecution of these offenders.

On motion, the national formulary was indorsed. A committee, consisting of Drs. J. G. Carpenter, of Stanford, Steele Bailey, of Stanford, and H. Hunt, of Lexington, was appointed to attend the meeting of the Pharmaceutical Association at Crab Orchard, May 15th.

A motion to hold the vote for officers with closed doors and by ballot, instead of committee, was voted down.

OFFICERS ELECTED.

*President*—John A. Ouchterlony, Louisville; *1st Vice-President*—William Jennings, Richmond; *2d Vice-President*—R. L. Willis, Lexington; *Permanent Secretary*—Steele Bailey, Stanford; *Assistant Secretary*—John Young Brown, Lexington; *Treasurer*—J. B. Kinnard, Lancaster. Henderson was chosen as the next place of meeting, and J. S. Letcher as Chairman of the Committee of Arrangements.

On the first evening of the session an elegant hop was given at the rooms of the Madison Club, and a banquet was served at the Garnett House on the evening of the second day. The master of ceremonies was Dr. Jennings,

of Richmond. Toasts were responded to as follows: "Our Guests," ex-Governor McCreary, of Richmond; "Medical Education," Dr. Dudley S. D. Reynolds, of Louisville; "The Young Doctor," Dr. J. M. Mathews, Louisville; "The American Doctor," Dr. W. H. Wathen, Louisville; "The Kentucky Doctor," Dr. L. S. McMurtry, Danville; "The Absent Ladies," Dr. O. D. Todd, of Eminence. The banquet was a success.

Greetings were sent the Michigan and Kansas State Medical Societies, then in session.

The attendance was very general from all parts of the State. Several prominent gentlemen at Louisville were not there, having been detained by the Louisville races.

Dr. Ap Morgan Vance made an interesting discourse on the subject of

THE ART OF ASEPSIS.

He showed the paraphernalia of the art and a very convenient case to carry when making calls or going into the country.

The report on

MEDICAL ETHICS

was made by Dr. Dudley S. Reynolds, of Louisville. He had looked into the requirements of this and other medical societies and found them quite exacting. Ethics are not law. The ethical penalty is censure, expulsion, ostracism. Ethics have no control over a man's property or personal rights. He thought the Code of Ethics excellent, and that the Secretary should place in the hands of every member of the Society a copy, and send it into the counties where there was no society.

Dr. Larrabee, of Louisville, had never heard that hydra-headed monster, medical ethics, made so pleasant as by Dr. Reynolds. He considered ethics the conduct of gentlemen. If a man is a gentleman he will need no ethics. If not a gentleman, ethics will not make him one.

The report on

OPHTHALMOLOGY

was made by Dr. S. G. Dabney, of Louisville. The advance during the past year, though nothing brilliant, had been steady. Cocaine has fairly held its own. The cataract operation with iridectomy was carefully discussed, also antiseptics in eye practice.

ACUTE TRAUMATIC TETANUS

was the subject of a paper by Dr. R. C. McChord, of Lebanon. He related some cases, and gave the results of treatment. He considered bromide of potash the best of all known remedies.

Dr. F. H. Clarke, of Lexington, had had half a dozen cases in his practice, and all proved fatal. He believed all cases traumatic.

Dr. Ap Morgan Vance, of Louisville, had seen a good many cases of traumatic tetanus, but never saw but one get well, which case he reported.

Dr. J. G. Carpenter, of Stanford, favored nourishing his patients. He kept them drunk on whiskey, so as to relax the spasms. One ounce of bromide of potassium in twenty-four hours had cured many cases.

Dr. J. G. Brooks, of Paducah, reported a case of traumatic tetanus which occurred in his practice while in the Hawaiian Islands. The subject was a Chinaman, who was nearly dying, and it was a case demanding kill-or-cure treatment, as the man was suffering terribly and begging to be killed. He gave him five grains of morphia, hypodermically. The next morning he was awakened by a crowd of Chinamen, who announced to him that the man was much improved. Two years later he was still all right.

Dr. J. A. Larrabee, of Louisville, said that he had had nine cases, four successful, and all children. He thoroughly believed that any case would yield to bromide of potassium, provided the remedy was given in sufficient dose. To the educated physician dosage is simply a botheration. He knows the physiological action and gives for results. The pathology of the disease is unknown.

Dr. Dudley S. Reynolds, of Louisville, was surprised to hear that any one thought the pathology of traumatic tetanus unknown. It was settled at the Second French Congress of Surgery, which met in Paris in 1886, by Professor Cornil, who presented the streptococcus as the cause, and his demonstration was so perfect that the Congress coincided totally with his belief. This great discovery should not be passed over lightly.

Dr. J. M. Matthews, of Louisville, thought the pathology of traumatic tetanus still very unsettled. He believed there was more to be learned by the report of cases. In one case he had given bromide of potassium, in sixty-grain doses, every second hour, for seven days, and continued the dose at greater intervals. At the end of three weeks the patient was able to go home.

THE MANAGEMENT OF WOUNDS

was the subject of a paper by Dr. C. C. Skinner, of Louisville. He favored irrigation.

Dr. T. Hunt Stuckey, of Louisville, thought that in some cases, circumcision for instance, irrigation favored œdema. He thought the dry dressing better in this case.

THE REPORT ON OTOLOGY

was made by Dr. J. M. Ray, of Louisville. He thought that medical men were now giving more time and attention to ear diseases. Many still treat the ear without giving the nose and throat especial study. The death of prominent men from diseases of these parts has called attention to these troubles.

Dr. J. G. Carpenter, of Stanford, thought the more aseptic and antiseptic we were the sooner will these troubles heal.

Dr. John Young Brown, of Henderson, reported a case of

OPERATION FOR IMPERMEABLE STRICTURE.

Dr. J. M. Foster, of Richmond, thought that the time was near when external urethrotomy would be a more common operation.

Dr. A. W. Johnstone said, Coxe's operation, though difficult, was not so much so as most men thought. He had made it three times, and all patients were living. A little courage was necessary. He was in favor of the use of the aspirator and trocar in some cases.

Dr. W. L. Rodman, of Louisville, favored the use of the aspirator.

"Ovarian Prolapse" was the subject of a paper by Dr. E. S. McKee, of Cincinnati.

A CASE OF TUBAL PREGNANCY WHICH ADVANCED TO TERM WITHOUT RUPTURE

was the subject of a report by Dr. A. Dixon, of Henderson. The case was one of exceptional difficulties of diagnosis. There was an enlargement which he thought an ovarian cystoma. He determined to make an exploratory laparotomy, and, to his surprise, opened up a sac which contained a macerated fœtus at full term. The post-mortem showed a case of tubal pregnancy, with no trace of any rupture. The case was a very rare one, and some deny the possibility of such occurring.

A case of "Tubal Pregnancy" was also reported by Dr. Charles M. Mann, of Nicholasville. His case resulted fatally, and a post-mortem was held.

A CASE OF EXTRA-UTERINE PREGNANCY

was reported by Dr. J. B. Evans, of Riley's Station. He was of the opinion that the ovule can become impregnated before it reaches the Fallopian tube, and then get into the abdomen. He believes the Fallopian tube can be contracted till it will admit of the passage of the spermatozoids, but not of the ovule. He reported a case of extra-uterine pregnancy in which a patient suffered long with peritonitis, and passed fœtal bones and other structures per rectum.

Dr. W. H. Wathen thought the case of Dr. Dixon unique, and could not see how it could possibly occur

that an extra-uterine pregnancy could be carried in the tube for this length of time. The tube walls are so thin and weak that by the twelfth week the tube ruptures, and the fœtus escapes into the abdominal cavity. He was sorry that Dr. Dixon did not make a thorough examination of the lining of the sac. He agreed with Tait that there was no possibility of an extra-uterine pregnancy unless it occurred in the tube, with possibly a chance for an ovarian pregnancy. It is utterly ridiculous to talk of an abdominal pregnancy occurring primarily. It has never occurred, and it never will occur. Extra-uterine pregnancy is tubal primarily. We have the electrical treatment and the operative treatment. He does not believe it possible to absolutely diagnose extra-uterine pregnancy before the twelfth week. It is mere guess-work before this time. He reported cases where physicians had fallen into error in diagnosing extra-uterine pregnancy when it was intra-uterine. He argued against the treatment by electricity, and said the only treatment was, when rupture occurs, operate at once and treat the case antiseptically. If it does not rupture, then laparotomy is the treatment.

Dr. J. G. Cecil could not understand how it was possible for Dr. Dixon's case to go on as he thinks it did. He thought a very fine dissection and microscopical examination would be necessary to substantiate the diagnosis. He could not agree with Drs. Wathen and Tait that there can be no primary cause of abdominal pregnancy. Undoubted cases are on record, and Tait is aware of them but fails to refer to them in his book. He thought the only thing which could be done was to perform abdominal section. The subject was further discussed by Drs. J. M. Foster, of Richmond, and E. S. McKee, of Cincinnati.

THE REPORT ON THE PROGRESS IN OBSTETRICS

was made by Dr. J. G. Cecil, of Louisville. He discussed in an able manner antiseptics in obstetrics, the delivery of the aftercoming head, in which he would hasten the delivery of the head with the forceps, even at the expense of the perineum and cervix. He discussed the third stage of labor, and the methods of Crédé and Ahlfield. He mentioned Berry Hart's theory, and recommended a compromise between Crédé and Ahlfield. He waits till the placenta separates, then, if there is any delay, uses Crédé's method. He discussed Cæsarean section *vs.* ovariotomy, and quoted from Busey's paper that the former was proper in all cases where the child was living. He favored abdominal section over electricity in extra-uterine pregnancy.

THE REPORT ON GYNECOLOGY

was made by Dr. W. H. Wathen, of Louisville. He confined his remarks to pelvic hæmatocele. He referred to the generally accepted definition of hæmatocele, viz., blood-tumor in the pelvis encapsuled within or without the peritoneal cavity. He said that all pelvic hæmatoceles were extra-peritoneal, and thus it is not possible for hemorrhage into the peritoneal cavity to become rapidly encysted so as to form a fixed tumor in the pelvic or the abdominal cavity; that the blood is mixed with lymph and coagulates so slowly that it is not confined in any one place in the cavity, but changes its position upon the movements of the body, obeying the laws of gravitation; that the blood could not be confined by a layer of effused lymph immediately above it; and that, if the hemorrhage into the cavity is at all considerable, death would probably result before it could be confined by adhesions of the superimposed intestines. Intra-peritoneal hemorrhage is nearly always fatal. Mr. Tait has seen nearly one hundred cases, and they all died except two, upon whom he did abdominal section. He referred to the fact that the blood never becomes encysted in intra-peritoneal hemorrhage from defective ligation in laparotomy for removal of the tubes, ovaries, etc. He gave as causes of encapsulated hæmatocele sudden metrostaxes of normal menstruation or of pseudo-menstruation following abdominal or pelvic operations and rupture of a tubal pregnancy. He said that intra-peritoneal hemorrhage is really always caused by primary or secondary rupture of ectopic gestation.

The tumor may extend out of the pelvis, and even as high up as the umbilicus, in extra-peritoneal hæmatocele. The peritoneum is a tough and elastic membrane, not readily ruptured, yet so easily separated from its attachments that hemorrhage in the loose pelvic connective-tissue may dissect up the tissue under the peritoneum between the broad ligaments, between the rectum and vagina, from around the rectum, from the sides of the pelvis, and from the anterior abdominal wall. In hemorrhage into the cavity of the peritoneum no well-defined tumor or fixation of the uterus can be felt in a bimanual examination; while in pelvic hæmatocele the symptoms are nearly pathognomonic.

He gave the symptoms and diagnosis of hæmotocele, and advised against surgical interference, unless the sac ruptures into the peritoneum or suppuration is imminent. If the fluctuation can be detected from below, he recommended making an opening giving free drainage in the vaginal vault, and if fluctuation is well marked above the pelvis, or ruptures occur into the peritoneum, an abdominal section should be done.

LARYNGEAL SYPHILIS

was the subject of a paper read by Dr. A. B. Thrasher, of Cincinnati. He said little difficulty would be experienced in the majority of cases, but occasionally the most skilful diagnosticians would be puzzled. The diseases most likely to be confounded with syphilis of the larynx are tubercle, cancer, and lupus.

In tubercle, and especially cancer, there is more pain than in syphilis. In cancer the pain is lancinating and radiates to the ear, and may be felt at any time. The voice is more changed in cancer and tuberculous disease. The classical pathognomonic syphilitic voice is usually more easily recognized when the acute observer has detected syphilis previously. Cough is much more pronounced in phthisis than in either the other conditions. Deglutition is more impeded in tuberculous or cancerous ulceration. The syphilitic ulcer develops rapidly in a few days, the cancerous requires weeks, and the tuberculous months. Syphilis attacks, preferably, the upper surface of the epiglottis, tubercle the under surface, cancer the ventricular band. In syphilis there is a solitary serpiginous ulcer with sharp edges, surrounded by an areola of hyperæmia; in tubercle there are numerous small, shallow ulcers, or these have run together forming a large ulcer with ragged, "nibbled" edges; the cancerous ulcer appears on the summit of an angry tumor, and is surrounded by highly inflamed tissue. In tubercle there is, as a rule, anæmia of pharyngeal and laryngeal mucosa, while hyperæmia is the rule in the other affections. Enlargement of cervical glands, anterior and posterior, is an indication of syphilis, and is either absent or not so marked in the other affections. Lupus of larynx might be mistaken for syphilis, yet the disease is so rare as not to fall within the observation of most laryngologists. When the only manifestation of lupus is in the larynx the administration of anti-syphilitic remedies might be required to insure the diagnosis.

THE REPORT ON SURGERY

was made by Dr. W. L. Rodman, of Louisville. The doctor in looking over the work in this department during the past year found himself surrounded by an embarrassment of riches. Senn's hydrogen-gas test he considered conspicuously the most brilliant, as it is perhaps the most useful. Gas finds its way out of the wound if there be perforation, and burns with a bluish flame. The twelve propositions of Senn were given. Senn's discovery has greatly increased the interest in penetrating wounds of the abdomen, and in the results we find much to cheer us. Suprapubic lithotomy has gained much in favor during the past year. Epicystotomy has every advantage for tumors and foreign bodies. The new cystoscope of Neitz and Leiter has rendered the diagnosis of tumors of the bladder comparatively easy. In cystitis of the female

More Madden, of Dublin, has recommended the dilatation of the urethra, then curette the proliferating mucous membrane and apply carbolic acid over its entire surface. In iliac abscess it seems that early operation promises the most. Dermoid cyst of the neck has been recently operated upon by Keetley, of London, by cutting away a portion of the cyst-wall suturing it to the neck, and stuffing it with gauze after cleansing it thoroughly. This has resulted well in his hands, and is certainly quicker and safer. Whitehead's method of operating for piles has here and there gained an earnest advocate, but will hardly supersede the ligature. Piles with prolapsus can perhaps be operated upon by Whitehead's method with the best advantage. Alexander's operation has fallen into disuse. It can only do good in cases of retroversion with fixation. Dr. Dudley, of New York, has recently described a new operation for rupture of the perineum. In the treatment of carbuncles Edmund Owen, of London, uses erasion. He cuts away all slough and undermined skin, scrapes thoroughly with a Volkmann's spoon, and dresses it antiseptically. In this way a painful and septic mass is converted into a painless and aseptic one. Excision of carbuncles is advocated by Gerster and others. The doctor considered it probably the best means of treating them. Cooles, of Dublin, has shown that changing from the horizontal to the sitting posture in injuries to patients with fracture of the bones of the lower extremities is very injurious. A new treatment of aneurisms has been suggested by Macewen. It consists of the introduction of needles into the sac till they reach the endothelial lining of the opposite wall. The oscillation of the needle scratches the endothelium and causes proliferation of the leucocytes, which are said to form a firm, fibrous mass. Pneumonotomy is gaining laurels for pulmonary abscess, fifty per cent. of the cases being successful. Pneumonectomy has met with such success in the lower animals that it is recommended in man. One lobe or a lung may be excised. It is thought that the minimal respiratory area compatible with life and health amounts to two pulmonary lobes. The past year has witnessed many sharp discussions as to the comparative merits of ether and chloroform. The latter has not suffered by the comparison. It is not desirable that one should supplant the other, as we need them both. One is good in some cases and inferior in others.

RECENT ADVANCES IN THE DIAGNOSIS AND TREATMENT OF TUBERCULOSIS

was the subject of a paper by Dr. F. C. Wilson, of Louisville. He referred to the frequency and distribution of the disease and the various methods of treating it, and the numerous instruments and apparatus for the same. He discussed Weigert's method of treating tuberculosis by breathing air at a temperature of 400 or 500 degrees Fahrenheit. He considered the ability of the patient to do this without harm to the tissues a marvel, but it was nevertheless true. He had not yet tried it, but he meant to do so. He favored the disinfection of every particle of the sputa, and great care to avoid infection of nurse or husband or wife.

Dr. J. N. McCormac, of Bowling Green, insisted on the disinfection or destruction of the sputa. For some time the Kentucky State Board of Health, of which he is secretary, has been distributing both to the laity and physicians, literature to the effect that tuberculous patients should be isolated and the sputa destroyed or disinfected. It is preferable to have the patient expectorate on paper and then burn the paper.

Dr. J. A. Larrabee, of Louisville, thought if the contagion was so great as described we should have more cases, especially of physicians who are treating laryngeal phthisis. At Brompton Hospital there are 4,000 persons treated annually, and no one of the physicians or nurses has contracted the disease. Mouth-breathing he thought one of the great causes of tuberculosis, that is, the shallow breathing which follows mouth-breathing.

THE TRANSMISSIBILITY OF TUBERCULOSIS

from the lower animals to man was the subject discussed by Dr. J. A. Ouchterlony, of Louisville, in a paper of considerable length and learning. This question was intimately connected with the subject of the infectiousness of the disease. The power of the bacillus to resist antiseptics is astonishing. Corrosive sublimate does not destroy the bacillus, even at the strength of 1 : 500. The theory of inheritance has been thoroughly shaken by the discovery of the bacillus. Tuberculosis is rarely if ever congenital, but acquired. If the former theory were true, the prospects of the removal would be remote indeed. If the latter be true, the prospects for the eradication of the disease are bright. We have clinical proof also that the disease is not congenital. The object of the paper was to show that tuberculosis could be transmitted from the lower animals to man. There can be no security from tuberculosis so long as tuberculous meat and milk are used. The disease is contagious, infectious, and not congenital. It is transmissible, especially through the alimentary canal and respiratory tract. Rabbits kept near tuberculous patients contract the disease in twenty-seven days. Rabbits suspended in cages so as to breathe the air exhaled by tuberculous cattle contract tuberculosis. The lungs are the primary seat of the infection. It may be contracted through the integument, mucous membrane, abraded epidermis, wounded and abraded surfaces. Tuberculosis in dumb animals is identical with tuberculosis in man. Transmissibility to other species is very frequent. The medical profession should inform the public of the condition of affairs and insist on the control of the meat and milk.

Speeches warmly commending the ideas presented in this paper were made by Drs. Reynolds, McCormac, and Carpenter; and on motion a committee, consisting of Drs. J. N. McCormac, Bowling Green; Dudley S. Reynolds, Louisville; John A. Ouchterlony, Louisville; and Wm. Bailey, Louisville, was appointed to bring this subject before the public.

THE IMPORTANCE OF RECTAL EXAMINATIONS TO LIFE INSURANCE COMPANIES

was a subject dealt with by Dr. Joseph M. Matthews, of Louisville. He considered it of great interest to life-insurance companies, and to those insured in them, that the examination be as thorough as possible. Most companies understand this, and have a long list of questions and examinations through which the applicant must go before he is admitted. No company, to his knowledge, requires a rectal examination. Many rectal diseases are incurable, and often fatal. The only thing the insurance companies do is to, in some instances, ask the question, Have you had piles or fistulæ. Piles and fistulæ are generally not very serious to life, and some other rectal diseases are. The doctor reported a number of cases which had come under his observation where insurance companies had lost money after a short period of insurance by neglecting the precaution of having a rectal examination made. The responsibility of the medical examiner for life insurance is a very grave one, and is too often overlooked. There are diseases affecting this portion of the body which are wholly unrecognizable save by a careful examination and the exploration of the rectum. There are diseases self-limited, incurable, and always fatal. The interim between their incipiency and full development is so vaguely marked, and the insidiousness so obscure, that nothing less than a full exploration will reveal their nature. If in this interim the patient were to apply for a life insurance policy he would probably be received into the company.

Dr. F. C. Wilson, of Louisville, thought it a delicate matter to ask this examination. It was with great reluctance that examination of the urine was introduced, but now no first class company fails to ask it, and it has saved them much money. He favored a middle ground. Question the patient, and if anything was found indicating trouble of this nature then make the examination.

THE PROGRESS MADE IN THE ENFORCEMENT OF THE NEW MEDICAL PRACTICE ACT

was the subject of a paper read by Dr. J. N. McCormac, Secretary of the State Board of Health. This has proven one of the most popular general laws ever passed in the State. Registration in most of the counties had been complete. Large numbers of charlatans, being unable to comply with the very reasonable and conservative provisions of the statute, had been compelled to leave the State, and scores of irregulars from all parts of the Union had been refused permission to practise in Kentucky. As was to be expected, the principal difficulty in its enforcement will occur in Louisville. The physicians of that city are making an organized effort to secure its strict enforcement, and there can be little doubt as to the final result. After the first of January he would publish an official medical directory of the State, giving the name, age, place of birth, address, and place and date of graduation of each physician in the State.

At the conclusion of the report the Society appropriated all the surplus in the treasury to be used, if the necessity occurs, to assist the physicians of any county where the law might be resisted, in enforcing its provisions.

"Syphilitic Ulceration of the Upper Air-passages" was the subject handled in an excellent manner by Dr. M. F. Coomes, of Louisville.

"Report on the Progress of Medicine" was made by Dr. J. W. Gilbert, of Lawrenceburg.

"Laparotomy for Penetrating Shot-wound of the Abdomen," by Dr. David Barrow, of Lexington.

"The Report on Vital Statistics" was made by Dr. T. B. Greenley, of West Point.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

ABDOMINAL PALPATION OF THE PLACENTA—OPERATIVE INTERFERENCE FOR SUPPURATION IN THE NEIGHBORHOOD OF THE CÆCUM—THE CROONIAN LECTURES AT THE COLLEGE OF PHYSICIANS—THE RELATIONSHIP BETWEEN CHEMICAL STRUCTURE AND PHYSIOLOGICAL ACTION—SHORTHAND FOR MEDICAL STUDENTS—DEATH OF DR. WOOLDRIDGE—DR. QUAIN, F.R.S.

London, June 18, 1889.

An interesting subject was discussed at the last meeting of the Obstetrical Society, viz., the possibility of determining the position of the placenta by means of abdominal palpation, and especially in cases of placenta prævia. A paper on the subject was read by Dr. Herbert Spencer, Assistant Obstetric Physician to University College Hospital. Two cases were described in which the author had been able to determine the site of the placenta by abdominal palpation, when it was situated in the upper segment of the uterus, and seven cases of placenta prævia were then described, in which the author had been able by abdominal palpation to diagnose the presence of the placenta in, or its absence from, the front wall of the lower segment of the uterus before a vaginal examination was undertaken, the diagnosis being verified afterward by vaginal and intra-uterine examination. All the seven cases were those of multiparæ, with head presentations, and the observations were made before the membranes were ruptured, without anæsthesia, and in the absence of pains. In three of the cases the exact site of the placenta on the front wall of the lower segment was ascertained by this method, and in two of these the placenta was felt at a time when it was impossible to feel it by the vagina. In the other four cases the placenta was diagnosed by abdominal palpation to be absent from the front wall. Dr. Spencer recommended that the examination should be made with the patient lying on her back, the bladder having previously been emptied; that it should be gentle, made in the absence of pains, and prolonged over several minutes, or, if necessary, repeated. The following conclusions had been arrived at by the author: In an ordinary vertex presentation (placenta in the upper segment), the occiput, forehead (at a higher level), and side of the head could, under favorable circumstances, be distinctly felt in the lower segment of the uterus by means of abdominal palpation. In a case of placenta prævia in which the head presented, the head was not felt where the placenta was situated, but was distinctly felt where the placenta was absent. When in front, the placenta was felt as an elastic mass of the consistence of a wetted bath-sponge, which kept the examining fingers off the head. Its edge might be felt, and had the shape of the segment of a circle. Within the circle all was obscure to the touch; outside the circle the head or other part of the child was plainly felt. Impulses to the head were not clearly felt through the placenta; impulses to the head through the placenta were distinctly felt at the spot from which the placenta was absent. The same applied to combined vaginal and abdominal examination.

A somewhat wandering discussion followed the reading of Dr. Spencer's paper. Dr. Braxton Hicks remarked that in one case of placenta prævia he had diagnosed the position some weeks before it was confirmed during delivery. Dr. Barnes said it had been observed that when the placenta was seated in the upper zones, and in front of the uterus, the uterine wall was thickened, and raised at the area of placental attachment, forming a hillock, which rose above the level of the smooth surface of the uterus. This was also confirmed by auscultation. Dr. Mathews Duncan said he had never succeeded with placental palpation. Placenta prævia was not the best condition to study it; far more favorable were the conditions of advanced healthy pregnancy in a multipara with a relaxed uterus and a thin abdominal wall. Dr. Champneys remarked that the value of Dr. Spencer's paper lay in the subsequent verification of the diagnosis made by palpation, though the cases were few. He believed auscultation was no guide whatever to the situation of the placenta. Dr. Herman observed that such placenta as those described by Dr. Spencer were the exception, and, as Müller had demonstrated, were generally thinner than usual and expanded.

At the last meeting of the Medical and Chirurgical Society an interesting communication was made by Sir Dyce Duckworth and Mr. John Langton. A boy was admitted into hospital with symptoms indicative of acute suppuration in the neighborhood of the cæcum. An operation was performed and the appendix vermiformis (which was gangrenous and also contained a fecal concretion) was removed. Some days later, in consequence of symptoms pointing to a fresh suppurative peritonitis on the left side, a median laparotomy was performed, and a collection of several ounces of pus was found in a large cavity bounded by agglutinated intestines. The abscess cavity extended deeply into the pelvic cavity. The patient made a complete, though tardy, recovery. The authors urged the importance of early operation when suppuration in the neighborhood of the cæcum was suspected, and the more so in cases of young adults as the cause was often the presence of some foreign substance in the appendix. They also spoke of the value of making the incision in the right linea semilunaris, as being more directly situated over the seat of the lesion than one made in the middle line.

The Croonian Lectures at the College of Physicians are now in course of delivery, Dr. Lauder Brunton being the lecturer for the present year, and the subject chosen by him being "The Relation between Chemical Structure and Physiological Action." In his first lecture he employed two homely similes to illustrate how either a rearrangement of, or a trifling alteration in, the chemical constituents of an organic compound might greatly change its nature. A closed pocket-knife was, he said, a harmless plaything; by opening one of the blades it was converted

into a dangerous weapon. The composition of the knife was exactly the same as before, but the relation of the parts to one another had been altered. So in chemistry, an alteration in the relation of the parts converted the comparatively harmless nitrile into the deadly isonitrile or carbylamine. By means of graphic formulæ we could represent diagrammatically the relative position of the atoms in a compound. Comparing ordinary formulæ with words, the lecturer remarked that, as with a comparatively small number of letters of the alphabet we were able to form a great number of words and to represent a great number of ideas, so, with a small number of elements we could form many compounds. Slight alterations in the composition of words, the introduction or abstraction of a single letter, would often completely change their meaning, and slight alterations in chemical substances would change their properties. By altering the arrangement of the letters we converted "room" into "moor," and thus got a very different idea. By making a slight addition to "moor" we got "Moorish," a word which, instead of conveying a sense of bleakness and coldness, brought before the mind ideas of oriental grandeur, sunshine, and activity. Similarly, in studying the physiological action of various chemical substances, we found that while usually certain alterations or additions only modified the action of the radical to a slight extent, yet now and again we met with cases where slight modifications produced an altogether unexpected effect. Thus sodium acetate had a very slight physiological action, but when one atom of hydrogen in the acetic-acid was replaced by bromine the result was mono-bromo-acetate of soda, which had a most remarkable action upon the muscles of the frog, rendering them rigid. Another example was phenol and aniline, both of which were markedly poisonous, but ortho-amido-phenol was innocuous.

The value of shorthand to medical students was recently brought before the General Medical Council by Sir Dyce Duckworth, who, however, was not the best advocate that could have been chosen, seeing that he is not himself a stenographer. With a view to ventilating the subject more fully, however, a committee has been formed, consisting of Sir Dyce Duckworth, Mr. Howard Marsh, Dr. Gowers, and Dr. Coupland. Some, at least, of these gentlemen are experienced shorthand writers. It is proposed to hold voluntary examinations among medical students and to offer prizes for proficiency.

I regret to record the very sudden illness and death of Dr. Wooldridge, Assistant Physician to Guy's Hospital, at the early age of thirty-one. Dr. Wooldridge was a Doctor, both of Science and of Medicine, of the University of London, and was favorably known as a rising physiologist.

Dr. Richard Quain, F.R.S., the projector and editor of "Quain's Dictionary of Medicine," has been appointed Physician Extraordinary to the Queen.

## OUR PARIS LETTER.

(From our Special Correspondent.)

GOOD NEWS FOR THE OLD FELLOWS—HOW TO MAKE THE OLD YOUNG AGAIN—REJUVENATION FROM HYPODERMATIC INJECTION OF TRITURATED TESTICLES—A NEW THEORY REGARDING MASTURBATION—LAVAGE OF THE PERITONEUM—THE ANTISEPTIC PROPERTIES OF THE HYDROCHLORATE OF PHENYLHYDRAZINE.

PARIS, June 28, 1889.

PROFESSOR BROWN-SÉQUARD has lately made a most extraordinary communication to the Société de Biologie of Paris, and to the Academy of Sciences, to the effect that he had obtained marvellous results by the injection into the subcutaneous cellular tissue of a liquid produced by the trituration of the testicles of young animals. M. Brown-Séquard declared that during the last ten years his general vigor had notably diminished, even more so than he had reason to expect, although he is in his seventy-third year. He was obliged to sit down after half an hour's work in a standing position in his laboratory, which he always left completely exhausted after having worked for two, three, or four hours in a sitting posture. To the great astonishment of all his assistants, he was able to work for nearly four hours, without feeling the necessity to rest himself, after the second injection that he had practised on himself; the bladder and the large intestine had also notably gained in strength. With the dynamometer he ascertained an incontestable augmentation of the strength of the limbs. Although he is now submitted to greater causes of fatigue than formerly, in the laboratory, he is no longer obliged, as was his wont, during the last ten years, to lie down, after meals which he took rather hastily in returning from his work of experimentation. Moreover, he affirmed that his intellectual work has become more easy, and that he has regained in this respect all that he had lost for several years. In other respects, also, he experienced a rejuvenescence of all his forces, physical and psychic, forces which had not been lost, but diminished, owing to advancing age. In short, he found himself possessed of the same vigor as he had enjoyed thirty years before. This communication has caused some sensation in the medical and lay press, and it has been pertinently asked by some writers in the latter why Professor Brown-Séquard gave the preference to the testicles of the guinea-pig to those of other animals for the composition he employed for the subcutaneous injections, and one of them suggested that it was perhaps owing to the prolific nature of these animals. At a subsequent meeting of the Society, Dr. Brown-Séquard endeavored to prove that the activity of the spermatic and physical and psychical vigor are connected, and in cases of senile impotence he recommends masturbation, to be practised once or twice a week, but in an incomplete manner; that is to say, it should not be allowed to be followed by ejaculation, although sufficient to produce some venereal spasm. Dr. Brown-Séquard had recently occasion to recommend this extraordinary practice to two gentlemen, one a solicitor and the other a notary, aged respectively fifty-eight and sixty-five years, who complained of premature loss of their venereal powers. Their genital organs were in a good state, and under the influence of this practice they partially recuperated their physical and intellectual forces. This result he could only attribute to the resorption by the organism of the products of secretion of the spermatic gland, but how long it will last, time alone will tell. This communication, made by such an eminent physiologist, was too much even for French modesty, and the lay press in particular was most severe in its criticisms against the author, condemning the remedy prescribed by him as being unphysiological and immoral. One writer suggested that Dr. Brown-Séquard ought to be reminded that senile atrophy, at the decline of life, invades all the organs, being a fatal consequence of the degeneration of the tissues of the heart; and that it is not by inoculation, even with the manufactured liquid extracted from the testicles of the guinea-pig, or any other animal, that one could hope to remedy this alteration.

Professor Trélat lately submitted to the Academy of Medicine the experimental researches of Dr. Delbet, Prosector, on "lavage," or washing out of the peritoneum. Dr. Delbet at first endeavored to determine the extent of the peritoneum which is bathed by the liquid in the lavage, then made an estimate of the quantity of liquid which remains in the peritoneum. Under the influence of the lavage neither the respiration nor the circulation appeared to be affected. Dr. Delbet then ascertained that the absorbing power of the peritoneum was considerable, liquids were absorbed with great facility and rapidity in the first twenty or thirty minutes. The liquid injected passes into the circulation, then, when the blood is super-hydrated, this power is arrested. There is then a moment which may be taken advantage of to pass without danger toxic substances into the peritoneal cavity. This view is absolutely confirmed by the following experiment: The author injected into the peritoneal cavity of a

dog a solution of the sulphate of strychnine, the animal was soon seized with convulsions and died in about five minutes. In another dog he repeated the same experiment after having previously injected a saline solution composed of seven per cent. of the chloride of sodium; the animal did not present any symptoms whatever of intoxication. This is owing to the fact that the serous membrane, having absorbed the first liquid, could not absorb the second. The knowledge of this property of the peritoneum is important, and leads to the conclusion that it will be possible, in surgical practice, to wash this membrane with antiseptic substances, a practice that surgeons had not dared to attempt till now.

Dr. Janet relates in the *Courrier Médical* a very grave and very curious case of hysteria. At the age of twenty years, a young girl who had already presented several manifestations of hysteria, was affected with absolute dysphagia. Nourished by a tube, she soon fell off in flesh, as she rejected the aliments ingested. Dr. Janet then treated her by hypnotism, and during the periods of sleep he was enabled to make her eat, but while she was awake the dysphagia returned. The doctor then adopted the plan of leaving her nearly all the time under the influence of the hypnotic sleep. There was created in this girl a sort of double existence, waking and hypnotic sleep. This latter existence appeared to get the better of her and to substitute itself for the first personality. Since the month of January last, this girl is under the influence of hypnosis and feels quite well, following her occupations as usual, and not suffering from dysphagia.

Dr. Marpmann draws attention to the antiseptic properties of the hydrochlorate of phenylhydrazine; added to milk in the proportion of 1 per 1,000, it preserves this liquid several days. It may not be applied to the preservation of alimentary substances, on account of its disagreeable savor and its toxic properties, when it is employed in any quantity. This antiseptic may replace the bichloride of mercury in medical practice. It does not precipitate milk, pus, albumen, gum, solutions of sugar, and consequently it presents an advantage over corrosive sublimate, which precipitates albuminous solutions.

## CAN NASO-PHARYNGEAL CATARRH BE CURED?

To the Editor of The Medical Record.

Sir: "B. R.," in The Medical Record of May 25th, seems inclined to look on my question as displaying a lack of appreciation of the many factors entering into the causation and aggravation of naso-pharyngeal catarrh. I will acknowledge the truth of his statements, but I think the question admits of a more definite reply than the one he gives, and if I interpret the ownership of the initials aright, I think "B. R." himself can, from his own experience, give such a reply.

That every organ in the body has a greater or less influence on every other requires no medical knowledge to assert. The amount and character of such influence in the individual case does require this knowledge.

The exciting cause of catarrh being a common cold (of course the predisposing cause, local or constitutional, is presupposed), the continuing cause may be a local malformation, chronic bronchial or pulmonic irritation, disease of the sexual organs, deficient activity of the excretory organs, feeble circulation with consequent cold extremities, any continuing irritation of the mucous tract below the pharynx, unhygienic habits or surroundings, which may be many and various, and, finally, the by no means unimportant neurotic diathesis, which was the one touched on in the case as stated in my first letter.

The continuing causes just enumerated are a few of the more important (prominent, at least), though not at all the only ones, considering, as was stated above, the immediate corporeal and the scarcely less near physical and spiritual (in the broad sense) environment.

Now, supposing all the more prominent complications mentioned, save the last one—the nervous diathesis—to be absent in a given case, what then would be the treatment?

That there are not other factors, in even such selected cases, aggravating the disease under discussion, it would be folly to say; but that the principal reason for the chronicity of the trouble in some patients is the nervous diathesis present, must, I think, be admitted.

Persons of such a type going to the more elevated districts, and breathing the rarer, and, consequently, dryer and more stimulating air, will find that any disease of the respiratory organs from which they may be suffering will be aggravated.

My own belief, of course, shared in common with others, is that, in this type, the only course which promises any amount of relief approaching to a cure lies in a change of climate. A mild, equable climate in a region near the sea, and near the sea-level, is the one to be sought.

By such means the constantly high-strung nervous system is placed in the least irritating surroundings, every part of the system drops more nearly to a healthy normal activity, and a little of nature's great healer, rest, is obtained by the mucous membrane of the nose and throat along with the other organs.

But this is not medical treatment in the common acceptation, and not one patient in twenty is able to seek the climate suitable to his condition.

What, then, is the best thing to do if the patient must remain in the unfavorable climate? The question asked of these specialists of much experience is not What would you do with this class of catarrhs? but What do you do with them?

As a matter of course, treatment is not restricted to local applications, but to be scientific must attack at any point presenting appearances of vulnerability. We will also predicate that it is the individual whom we are to treat, and that the disease is not to be attacked in exactly the same way we would attack an enemy trying to scale the walls of a fort. Without further explanations I will say that if any one is kind enough to reply to this, I hope that he will not devote any time to dissecting my article, but will charitably forego that easy pleasure and give his pen entirely to the question asked. I would refer such a one to my letter in The Medical Record of May 18th for a more explicit statement of the exact variety of naso-pharyngeal catarrh about which inquiry is made.

G. P. Head, M. D.

## THE INTERNAL USE OF CHLOROFORM.

To the Editor of The Medical Record.

Sir: Your editorial "On the Internal Use of Chloroform," in the No. for the 8th ult., and the many articles that have lately appeared in the medical journals on that subject, all advocating the use of the remedy in small and largely diluted doses, prompt me to call attention to an article "On the Use of Chloroform as an Internal Remedy," by A. P. Merrill, M.D., of Memphis, in *The American Journal of the Medical Sciences*, October, 1865. Dr. Merrill advises its administration in large (teaspoonful and even greater) doses and undiluted, in many cases of disease, especially "in every kind of convulsive movement," and in the "chill stage of all fever, in its most fatal and epidemic form." Let me quote a few passages from this paper: "Objection is sometimes made to the introduction of unmixed chloroform into the stomach, on account of its highly excitant quality. But experience proves it to be much less stimulating to the mucous membrane than to the skin, and in no case have I observed anything more than very temporary effects upon the mouth and throat, which soon subside. The vehicles we are advised to employ in its administration can only hold the remedy in temporary suspension, and in most of the cases requiring large doses it is quite impossible for the patient to swallow them. Sometimes a single drop falling

into the folds of the neck will cause vesication, while a fluidrachm passing into the stomach gives only a slight inconvenience by its stimulation of the mouth and throat. As in the administration of other remedies, the dose of chloroform must be varied according to the nature of the case, and more than with most other remedies may be the range of quantities given. I have administered it in doses of a single drop to two fluidrachms, and have sometimes repeated it at short intervals; and I have reason to believe that the cases of infantile convulsions in which I have given from one-half to a full drachm, might have been relieved in the inception of the disease by fifteen or twenty drops. But when convulsions have continued for an hour or more, the smaller doses will have no perceptible effect. Indeed, relief in such cases is obtained only by such quantity as will produce sleep. The sleep continues from one to four hours, and is sometimes followed by great restlessness and jactitation for an hour or more, when the patient is at ease again and sleep returns." Dr. Merrill gives particulars of fourteen cases in which a teaspoonful of undiluted chloroform was successfully administered, and in some of them the same dose was repeated in half an hour. The ages reported in these cases vary from a child of a year and a half to "an elderly lady, very fat and plethoric." Of these fourteen cases, five had convulsions, three had chills, two were poisoning by strychnine, and one each of asthma, sunstroke, epilepsy, and fit of cramp-colic. I will relate Case VI. as a "specimen brick:" "A child, aged about two years, was taken with a convulsion while riding in a little hand-carriage, supposed effect of a chill, although the child had not had chills previously. When I arrived her mother and others thought the fit had continued two hours. She had been several times in a hot bath. Sinapisms had been extensively applied, and a physician was administering chloroform by inhalation without effect. The pulse was hardly perceptible, the eyes open and bloodshot, pupils dilated, skin of a purple color, jaws clinched, fingers and toes tightly drawn inward, and the whole frame severily convulsed. I administered a teaspoonful of chloroform by the mouth, the physician present admonishing me of the probable violence to the mucous membrane and of her inability to swallow, and a few minutes afterward as much more was given by enema. Very soon she was quite relieved of all spasmodic action, and in a sound sleep. A dose of calomel at night, and quinine for several successive mornings, completed the cure." Since the publication of Dr. Merrill's article I have often prescribed chloroform in similar doses, and never with any unpleasant result, but have uniformly found it very serviceable in proper cases. For the distressing pain of congestive dysmenorrhœa I consider it a specific. It will give prompt relief from the awful agony of bilious colic, and in epileptic and infantile convulsions, it "acts like a charm." A teaspoonful of undiluted chloroform, followed by no drink of any kind, is a hot dose; but the pungent effect is but momentary. Finally; I would urge the readers of THE RECORD to give it a fair trial, confident that they will find it of vast service.

T. C. WALLACE, M.D.

CAMBRIDGE, N. Y., June 12, 1889.

ELECTROLYSIS IN STRICTURE OF THE URETHRA.—Dr. J. A. Fort, of Paris, France, writes: "In THE MEDICAL RECORD for April 13th I read, on page 418, an account of my operation on stricture of the urethra by electrolysis. It is stated in that article that one of my colleagues, Dr. Lavaux, recorded the frequency of relapses after this operation. In that statement there is a serious mistake which it is impossible for me to allow to pass without protest. This gentleman, Doctor of Medicine only for the last five months, never saw a single relapse after any of my operations, the relapses of which he speaks followed operations performed in a different manner and by other surgeons. I operate after a new method and possess notes of 550 cases, and I have not yet recorded a single certain relapse."

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 30 to July 13, 1889.*

TEN EYCK, BENJAMIN L,. First Lieutenant and Assistant Surgeon (recently appointed). By direction of the Acting Secretary of War, will proceed from New York City to Fort Leavenworth, Kan., and report for duty to the commanding officer of that post. Par. 2, S. O. 138, A. G. O., Washington, D. C., June 15, 1889.

CORSON, J. K., Major and Surgeon. Granted leave of absence for one month, with permission to apply for an extension of one month. Par. 2, S. O. 65, Headquarters Department of the Columbia. The above leave of absence extended one month. Par. 1, S. O. 45, Division of the Pacific, June 24, 1889.

HOFF, JOHN VAN R., Captain and Assistant Surgeon, is relieved from duty at Fort Reno, Ind. Ter., and ordered to Fort Riley, Kan. Par. 6, S. O. 145, A. G. O., Washington, D. C., June 24, 1889.

BACHE, DALLAS, Major and Surgeon, is relieved from duty at Fort Riley, Kan., and ordered to report to commanding general, Department of the Platte, for duty as medical director of that department. Par. 6, S. O. 145, A. G. O., Washington, D. C., June 24, 1889.

WOODRUFF, EZRA, Major and Surgeon. By direction of the Secretary of War is relieved from temporary duty at Fort Monroe, Va., and will report in person to the commanding officer at Fort Hamilton, N. Y., for duty at that station. Par. 5, S. O. 146, A. G. O., June 25, 1889.

FISHER, WALTER W. R., Captain and Assistant Surgeon. By direction of the Secretary of War, the extension of leave of absence granted in S. O. 41, June 12, 1889, Division of the Pacific, is still further extended fifteen days. Par. 8, S. O. 146, A. G. O., Washington, June 25, 1889.

CHAPIN, A. R., Captain and Assistant Surgeon. Leave of absence for twenty-five days, to commence on or about July 2, 1889, is granted. Par. 6, S. O. 145, Division of the Atlantic, June 27, 1889.

GIBSON, R. J., Captain and Assistant Surgeon. Reports arrival, July 2, 1889, at Camp Lewis, Fisher's Island, N. Y., in compliance with Par. 5, S. O. 133, Division of the Atlantic, which designated him as M. O. for the encampment (rifle practice) at Fisher's Island, N. Y.

CHERBONNIER, ANDREW V., Captain and Medical Storekeeper. By direction of the Secretary of War, will, in addition to his present duties, take charge of the office and perform the duties of Acting Assistant Medical Purveyor in St. Louis, Mo., during the absence of Captain George T. Beall, Medical Storekeeper. Par. 2, S. O. 151, A. G. O., July 2, 1889.

GORGAS, H. C., Captain and Assistant Surgeon. Leave of absence for one month is granted, to take effect on the arrival of a medical officer to relieve him. Par. 2, S O. 84, Headquarters Department of the Missouri, July 3, 1889.

BEALL, GEORGE T., Captain and Medical Storekeeper. By direction of the Secretary of War, leave of absence for two months is granted. Par. 8, S. O. 148, A. G. O., June 27, 1889.

MCPARLIN, THOMAS A., Colonel and Surgeon. By direction of the Acting Secretary of War his retirement from active service, this date, by operation of law, under the provisions of the Act of Congress approved June 30, 1882, is announced. Colonel McParlin will repair to his home. Par. 2, S. O. 157, A. G. O., July 10, 1889.

SMITH ANDREW K., Colonel and Surgeon. Promoted Surgeon, with rank of Colonel, to rank from July 10, 1889. Vice McParlin, retired.

TOWN FRANCIS L., Lieutenant-Colonel and Surgeon. Promoted Surgeon, with rank of Lieutenant-Colonel, to rank from July 10, 1889. Vice A. K. Smith, promoted.

PERLEY, H. O., Captain and Assistant Surgeon. Ordered to accompany troops from Fort Wayne, Mich., to Gognac Lake, Mich., to encamp there with the Michigan State troops, from August 8, to 13, 1889. Par. 1, S. O. 154, Headquarters Division of the Atlantic, July 9, 1889. Granted fourteen days' leave of absence, to commence about July 14, 1889. Par. 2, S. O. 154, Headquarters Division of the Atlantic, July 9, 1889.

---

*Official List of Changes in the Medical Corps of the United States Navy for the week ending July* 13, 1889.

WHITE, S. STUART, Assistant Surgeon. Detached from the Trenton, July 7, 1889. Ordered to the Naval Hospital, Brooklyn, N. Y.

WHITE, C. H., Medical Inspector. Detached from the Trenton, and wait orders.

NORFLEET, ERNEST, Passed Assistant Surgeon. Detached from the Trenton, and to the Monocacy.

AMES, H. E., Passed Assistant Surgeon. Detached from the Monocacy, proceed home, and wait orders.

HARRISON, G. E. H., Surgeon. Detached from the Constellation, and to the Naval Academy.

LOWNDES, C. H. T., Assistant Surgeon. Detached from the Constellation, and to the Naval Academy.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 13, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 18 | 4 |
| Scarlet fever | 47 | 10 |
| Cerebro-spinal meningists | 2 | 3 |
| Measles | 49 | 4 |
| Diphtheria | 84 | 28 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

THE NORTHERN KANSAS MEDICAL SOCIETY held its fifth annual session at Seneca on the 9th inst. Dr. A. G. Edwards, of Marysville, read a paper on "Fractures and their Complications, of the Femur, Tibia, and Fibula." Dr. H. P. Porter, of Oneida, spoke on "The Disabilities of Old Soldiers." Dr. Grant Cullimore, of Atkinson, advocated, from successful experience, the use of the lead-coil pipe in cases of mastoiditis, through which iced water was caused to flow. In this connection the case of the Hon. Roscoe Conklin was instanced as a favorable one for successful treatment by this method. Dr. W. F. Richardson, of Havensville, reported a case of "Deafness following Measles." Specialists of Topeka and St. Joseph had treated this case without improvement. A gun was accidentally discharged in proximity to the child, when she exclaimed, "I can hear! I can hear!" The case was one in which there was thought to be collapse of the membrane, with slight adhesions, or possibly a closure, from like cause, of the Eustachian tube. Dr. M. M. Wachter, of Baileyville, read a paper on "Cholera Infantum." Dr. E. W. Bliss, of Hiawatha, reported a case of "Retention of Urine." The catheter had been used, but without relief. Paracentesis in the supra-pubic region effected the desired result. The cannula of a small trocar was left in the puncture for three days, when urine was voided through the natural channel, and complete recovery rapidly followed. He also spoke of a case of hernia now under treatment. Some three weeks ago he cut over a strangulated hernia, and found the bulk of the tumor omental; but a knuckle of the bowel was also found which was so tightly constricted that the abdominal ring had to be incised to effect reduction. The protruding omentum was ligated, cut off, and the stump left in the sutured wound, which yet remained unclosed. At 10 P.M. the proceedings became informal. The subject of advertising, such as giving cases to the public press, was freely discussed and forcibly condemned. Consultations with "irregulars" was also debated, and as severely censured. Resolutions on the death of Dr. C. J. Logie, of Hiawatha, were adopted, and the Society adjourned, to meet again at Seneca, on the 14th of November next. Dr. William Strayer, Secretary of the Society, in sending us a report of the meeting, writes: "Our membership extends from St. Joseph, Mo., to Fairbury, Neb. Some of the most prominent physicians of Northern Kansas are active members. We have been termed the 'rowdy West,' and it is likely the shoe fits when we wish to carry a political convention; but we believe that our medical societies, and especially the Northern Kansas, are conducted with as much dignity and decorum, and possibly as much erudition evinced, as some Eastern societies. Our Eastern brethren are better known to us than we are to them, and one reason for this is, that they are, or have been, more ambitious or enterprising than we in having their society proceedings published in journals that we both take."

THE REMOVAL OF HAIR BY ELECTROLYSIS.—Dr. Richard B. Faulkner, of Allegheny, Pa., writes: "Now that the use of electrolysis has become so common in the removal of facial blemishes, it seems prudent to advise the exercise of very great care in its application. The face is always a very important part. Should a surgeon accidentally mar its beauty, its financial value, as expressed in a suit for malpractice, cannot be estimated. To do no harm should be our first consideration; and the more important this matter becomes, as the more fastidious and aristocratic the bearer of the face happens to be. In the removal of hair, too much electric power, and needles of too large a size, will sometimes occasion minute cicatricial fibroid nodules, distinctly to be felt as little lumps; and I have no doubt will be plainly seen as age advances as elevations upon the lips of those from whom mustaches have been removed. Again, more electric power than just enough to remove the hair intended to be removed, will, in proportion, stimulate the growth of other hair in adjacent follicles. Care is always required that the positive current be not used, lest you bore a permanent hole in some fine lady's cheek. In the electrolytic removal of hair, moles, wine-marks, warts, etc., the mildest power that is capable of doing the work is the safest. The tension current is the electrolytic current. And it would be well if all writers would speak of the various cells used, as compared to the standard cell of Daniell. I use the excellent diamond carbon cell. Each cell equals 1.75 Daniell cells. Two to four diamond carbon cells are sufficient to remove hair; two to eight, moles; six to ten, wine-marks. Silver needles are the best conductors, and give the least pain. Cocaine solutions dry upon and crust the surface, and are inappropriate for dermal anæsthesia."

HEALTHY NEW YORK GIRLS.—Said a gentleman from a small country town in Massachusetts to me recently: "Talk about delicate New York women! Why, I see more healthy women on Fifth Avenue in two hours than I see in Massachusetts in a year."—*The Epoch.*

## Original Articles.

### CONSIDERATIONS CONCERNING SOME EXTERNAL SOURCES OF INFECTION IN THEIR BEARING ON PREVENTIVE MEDICINE.[1]

BY WILLIAM H. WELCH, M.D.,

PROFESSOR OF PATHOLOGY IN JOHNS HOPKINS UNIVERSITY, BALTIMORE, MD.

No department of medicine has been cultivated in recent years with such zeal and with such fruitful results as that relating to the causes of infectious diseases. The most important of these results for preventive medicine and for the welfare of mankind is the knowledge that a large proportion of the causes of sickness and death are removable.

It is evident that efforts to preserve health will be most intelligently and effectually applied when they are based upon an accurate and full knowledge of the agencies which cause disease. Public and private hygiene, however, cannot, and, fortunately, has not waited for the full light of that day whose dawn has only begun to appear, when we shall have a clear insight into the causation of preventable diseases. Cleanliness and comfort demand that means shall be taken to render pure the ground on which we live, the air which we breathe, and the water and food with which we are supplied, and we must meet these needs without waiting to learn just what relation infectious agents bear to the earth, air, water, and food.

It is a fortunate circumstance that modern sanitation has been controlled so largely by the belief in the dependence of endemic and epidemic diseases upon organic impurities in the soil and in the water. Incomplete and even erroneous in many respects as are the views which have prevailed concerning the origin and spread of epidemic diseases by the decomposition of organic substances, the sanitary measures which have been directed toward the removal of filth have achieved great conquests in limiting the development and extension of many infectious diseases. The benefits which one commonwealth of this country has derived from the intelligent employment of public sanitary measures were clearly and forcibly presented before this Association, last year, by Dr. Walcott, in his admirable address on "State Medicine."

While nothing should be said, or need be said, to lessen the importance of cleanliness for public health, it is important to bear in mind that hygienic cleanliness and æsthetic cleanliness are not identical. In water which meets the most severe chemical tests of purity typhoid bacilli have been found. On the other hand, the air in the Berlin sewers, which certainly does not meet the most modest demands of æsthetic cleanliness, has been found to be nearly or quite free from bacteria.

It needs only to be stated to be generally admitted that the scientific basis of preventive medicine must be the accurate knowledge of the causative agents of preventable diseases, a knowledge which can be derived only from a careful study of all of the properties of these agents, the modes of their reception and of their elimination by the body, the circumstances which favor and those which retard or prevent their development and spread, their behavior in the various substances which surround us, or which we take into our bodies, and the sources of infection, not only those which laboratory experiments show to be possible, but those which are actually operative.

So long as we were unacquainted with the living organisms causing infection, the means at our disposal for studying the etiology of infectious diseases were limited to the observation of all of the circumstances which we could determine regarding the origin and spread of these diseases. We could only infer what might be the properties of the infectious agents from the study of phenomena often obscure and difficult of interpretation. Chiefly by this method of investigation the science of epidemiology has been built up. It has established facts and laws no less of practical than of scientific importance. But it has left unsolved many problems, and has filled gaps with speculations. Admitted epidemiological facts are often open to various interpretations.

We are evidently at a great advantage when we can study the epidemiological facts with a knowledge of the substances which actually cause infection, and this we are now enabled to do for a limited number of the infectious diseases. This new method of research, which thus far has been mainly bacteriological, has aided us not so much by simplifying the problems of etiology, which still remain complicated enough, as by affording greater accuracy to the results.

It is my aim in this address to consider some results of the modern studies of pathogenic micro-organisms in their bearing upon preventive medicine, more particularly upon the sources of infection. It is, of course, impossible within the limits of the address to attempt a complete survey of this important field. Time will permit the presentation of only some of the salient points.

Infectious diseases are those which are caused by the multiplication within the body of pathogenic micro-organisms.

It has always been recognized that some infectious diseases, such as the exanthematous fevers, are conveyed directly from the sick to the healthy. It is not disputed that in these evidently contagious diseases the infectious germ is discharged from the body in a state capable at once of giving rise to infection.

In a second group of infectious diseases, of which malaria is the type, the infected individual neither transmits the disease to another person, nor, so far as we know, is capable of infecting a locality. Here there is reason to believe that the infectious germ is not thrown off in a living state from the body, but is destroyed within the body. In this group the origin of infection under natural conditions is always outside of the body.

In a third group there is still dispute whether the disease can be transmitted directly from person to person, but all are agreed that the infected individual can infect a locality. It is especially fortunate that the bacteria which cause cholera and typhoid fever, the two most important representatives of this group of so-called miasmatic contagious diseases, have been discovered and isolated in pure culture. These are the diseases about whose origin and epidemic extension there has been the greatest controversy. They, above all other diseases, have given the impulse to public sanitation during the last half-century. The degree of success with which their extension in a community is prevented is an important gauge of the excellence of the local sanitary arrangements. A clear comprehension of the origin and spread of these diseases signifies a solution of many of the most vexed and important problems of epidemiology and of State hygiene.

[1] Address in State Medicine, delivered before the American Medical Association, in Newport, on Friday, June 28, 1889.

It is difficult to understand how those who accept the discovery that the bacteria causing typhoid fever and cholera have been found and cultivated from the stools of patients affected with these diseases can doubt that these patients are possible sources of contagion, or can entertain the view, once so widely prevalent, that the infectious germs of these diseases are discharged from the body in a condition incapable of producing immediate infection. In an address delivered on another occasion, I have endeavored to present the considerations which reconcile the comparative infrequency of direct contagion for these diseases with the belief in the elimination of the causative germs in an active state from the body, and have there pointed out several well-known factors which determine the frequency of conveyance of an infectious disease by contagion. There are reasons, some of them very obvious, why diseases in which the infectious substances are operative only when received into the digestive tract, and are discharged usually only with the fæces, are less likely to be transmitted by immediate contagion than those diseases in which the virus is thrown off from the skin on epidermal scales.

But the field of operation of direct contagion for those so-called miasmatic contagious diseases is at most a restricted one, and the chief sources of infection are outside of the body from which primarily the infectious germs may have been derived. It is to these external sources of infection, which are of such importance in public hygiene, that I wish especially to direct attention.

A full comprehension of the sources of infection is, of course, to be obtained only by a detailed study of the etiology of the individual infectious diseases; but this is, of course, impossible within the limits of an address. It may, however, be useful to present some of the facts which have a general bearing upon the subject. Let us consider, then, from the point of view of modern bacteriological studies, what rôle in harboring or transporting infectious agents may be played by those substances or media with which we necessarily come into intimate contact, such as the air, the ground, the water, and our food.

It is universally admitted that many infectious agents may be transported by the air, but the extent of danger from this source has often been exaggerated. It is a popular error to suppose that most of the minute particles of dust in the air either are or contain living organisms. The methods for determining the number and kind of bacteria and fungi in the air are now fairly satisfactory, although by no means perfect. These have shown that while the number of living bacteria and fungi in the atmosphere in and around human habitations cannot be considered small, still it is greatly inferior to that in the ground or in most waters. Unlike fungus spores, bacteria do not seem to occur to any extent in the air as single detached particles, which would then necessarily be extremely minute, but rather in clumps or attached to particles of dust of relatively large size. As a result, in a perfectly quiet atmosphere these comparatively heavy particles which contain bacteria rapidly settle to the ground or upon underlying objects, and are easily filtered out by passing the air through porous substances, such as cotton-wool or sand. Rain washes down a large number of the bacteria from the air. That the air-bacteria are derived from the ground, or objects upon it, is shown by their total absence, as a rule, from sea-air at a distance from land, this distance naturally varying with the direction and strength of the wind.

A fact of capital importance in understanding the relations of bacteria to the air, and one of great significance for preventive medicine, is the impossibility of currents of air detaching bacteria from moist surfaces. Substances containing pathogenic bacteria, as, for instance, sputum containing tubercle bacilli, or excreta holding typhoid bacilli, cannot, therefore, infect the air unless these substances first become dry and converted into a fine powder. We are able to understand why the expired breath is free from bacteria and cannot convey infection, except as little particles may be mechanically detached by acts of coughing, sneezing, or hawking. Those bacteria, the vitality of which is rapidly destroyed by complete desiccation, such as those of Asiatic cholera, evidently are not likely to be transported as infectious agents by the air, if we except such occasional occurrences as their conveyance for a short distance in spray.

The only pathogenic bacteria which hitherto have been found in the air are the pus-organisms, including the streptococcus found by Prudden in a series of cases of diphtheria and tubercle bacilli; but no far-reaching conclusions can be drawn from the failure to find other infectious organisms when we consider the imperfection of our methods and the small number of observations directed to this point. The evidence in other ways is conclusive that many infectious agents—and here the malarial germ should be prominently mentioned—can be, and often are, conveyed by the air. While we are inclined to restrict within narrower limits than has been customary the danger of infection through the air, we must recognize that this still remains an important source of infection for many diseases. All those, however, who have worked practically with the cultivation of micro-organisms have come to regard contact with infected substances as more dangerous than exposure to the air, and the same lesson may be learned from the methods which modern surgeons have found best adapted to prevent the infection of wounds with the cosmopolitan bacteria which cause suppuration.

We are not, of course, to suppose that infectious germs floating in the form of dust in the atmosphere are dangerous only from the possibility of our drawing them in with the breath. Such germs may be deposited on substances with which we readily come into contact, or they may fall on articles of food where they may find conditions suitable for their reproduction, which cannot occur when they are suspended in the air, in consequence of the lack of moisture.

From the facts which have been mentioned concerning the relations of bacteria to the air, what points of view present themselves to guide us in preventing infection through this channel? Surely something more than that this purpose is accomplished simply by abolishing foul odors.

Certain indications are so plain as to need only to be mentioned in this connection, such as the disinfection and removal, as far as possible, of all infected substances, an indication which applies equally to all channels of infection, and which is much easier to mention than it is to describe how it shall be realized. But there are two indications which apply especially to the prevention of the transportation of disease-germs by the air. One is the necessity of guarding, so far as practicable, against the desiccation, when exposed to the air, of substances which contain infectious germs not destroyed by drying, and another is free ventilation.

For no disease is the importance of the first of these indications so evident and so well established as for tuberculosis, the most devastating of all infectious diseases. Against this disease, formidable as it may seem to cope with it, the courageous crusade of preventive medicine has begun and is destined to continue.

It is now generally recognized that the principal, although not the sole, sources of tuberculous infection are the sputum of individuals affected with pulmonary tuberculosis and the milk of tuberculous cows. Cornet, who has made a laborious and most instructive experimental study of the modes and dangers of infection from tuberculous sputum, has also elaborated the practical measures which should be adopted to diminish or annihilate those dangers. These measures have been so recently and so widely published in medical journals, and so clearly presented before a Section of this Association, that I mention them only to call the attention of practitioners of medicine to their importance, and to emphasize the fact that they are based chiefly upon the principle that infectious sub-

stances of such nature as tuberculous sputum should not be allowed to become dry and converted into dust when exposed to the air.

By means of free ventilation disease-producing micro-organisms which may be present in the air of rooms are carried away and distributed so far apart that the chance of infection from this source is removed or reduced to a minimum. It is a well-established clinical observation that the distance through which the specific microbes of such diseases as small-pox or scarlatina are likely to be carried from the patient by the air, in such concentration as to cause infection, is small, usually not more than a few feet, but increase by crowding of patients and absence of free ventilation. The well-known experiences in the prophylaxis and treatment of typhus fever are a forcible illustration of the value of free ventilation.

It is, of course, not to be understood that by ventilation we accomplish the disinfection of a house or apartment. Ventilation is only an adjunct of such disinfection, which, as already mentioned, is of first importance. Time will not permit, nor is it in the plan of this address, to discuss the details of such questions as house disinfection, but I may be permitted to say that the methods for disin fecting apartments have been worked out on a satisfactory experimental basis, and should be known, at least, by all public-health officers. Whether it be pertinent to this occasion or not, I cannot forbear to add my protest to that of others against placing reliance upon any method hitherto employed of disinfecting houses or apartments by fumigation. And I would furthermore call attention to the lack in most cities of this country of public disinfecting establishments such as are in use with excellent results in most cities of Europe, and which are indispensable for the thorough and convenient disinfection of clothing, bedding, carpets, curtains, etc.

After this short digression, let us pass from the consideration of the air as a carrier of infection to another important external source of infection, namely, the ground. That the prevalence of many infectious diseases depends upon conditions pertaining to the soil cannot be questioned; but the nature and the extent of this influence have been and are the subjects of lively discussion. The epidemiological school led by Pettenkofer assigns, as is well known, to the ground the chief, and even a specific and indispensable influence, in the spread of many epidemic diseases, particularly cholera and typhoid fever. The statistics, studies, and speculations of epidemiologists relating to this subject probably surpass in number and extent those concerning any other epidemiological factor. The exclusive ground-hypothesis has become an ingenious and carefully elaborated doctrine with those who believe that such diseases as cholera and typhoid fever can never be transmitted by contagion. These authorities cling to this doctrine with a tenacity which indicates that on it depends the survival of the exclusively localistic dogma for these diseases.

To all who have not held aloof from modern bacteriological investigations it must be clear that views which have widely prevailed concerning the relations of many infectious germs to the soil require revision. The question is still a difficult and perplexing one, but on some hitherto obscure or misunderstood points these investigations have shed light, and from the same source we may expect further important contributions to a comprehension of the relations of the ground to the development of infectious diseases.

The ground, unlike the air, is the resting- or the breeding-place of a vast number of species of micro-organisms, including some which are pathogenic. Instead of a few bacteria or fungi in a litre, as with the air, we find in most specimens of earth thousands, and often hundreds of thousands, of micro-organisms in a cubic centimetre. Fraenkel found the virgin soil almost as rich in bacteria and fungi as that around human habitations. This vast richness in micro-organisms belongs, however, only to the superficial layers of the earth. Where the ground has not been greatly disturbed by human hands there is, as a rule, about three to five feet below the surface an abrupt diminution in the number of living organisms, and at the depth where the subsoil water usually lies bacteria and fungi have nearly or entirely disappeared. Fraenkel, who first observed this sudden diminution in the number of micro-organisms at a certain level beneath the surface, explains this singular fact by the formation at this level of that sticky accumulation of fine particles, consisting largely of bacteria, which forms the efficient layer in large sand-filters for water. Of course, the number of bacteria and the depth to which they penetrate will vary somewhat with the character, especially the porosity of the soil and its treatment; but the important fact that all, or nearly all, of the bacteria and fungi are retained in the ground above the level of the subsoil water will doubtless hold true for most situations.

The conditions are not favorable for the multiplication of bacteria in the depth of the ground, as is shown by the fact that in specimens of earth brought to the surface from a depth of a few feet, the bacteria which are at first present rapidly multiply. What all of the conditions are which prevent the reproduction of bacteria in the deep soil has not been ascertained, but the fact necessitates similar precautions in the bacteriological examination of the soil as in that of water.

We have but meagre information as to the kinds of bacteria present in the ground in comparison with their vast number. Many of those which have been isolated and studied in pure culture possess but little interest for us, so far as we know. To some of the micro-organisms in the soil appears to be assigned the rôle of reducing or of oxidizing highly organized substances to the simple forms required for the nutrition of plants. We are in the habit of considering so much the injurious bacteria that it is pleasant to contemplate this beneficent function so essential to the preservation of life on this globe.

Among the pathogenic bacteria which have their natural home in the soil the most widely distributed are the bacilli of malignant œdema and those of tetanus. I have found some garden-earth in Baltimore extremely rich in tetanus bacilli, so that the inoculation of animals in the laboratory with small bits of this earth rarely fails to produce tetanus. In infected localities the anthrax bacillus, and in two instances the typhoid bacillus, so far as it was possible to identify it, have been discovered in the earth. There is reason to believe that other germs infectious to human beings may have their abiding-place in the ground; certainly no one doubts that the malarial germ lives there. As the malarial germ has been shown to be an organism entirely different from the bacteria and the fungi, we cannot apply directly to its behavior in the soil, and its transportation by the air, facts which have been ascertained only for the latter species of micro-organisms, and the same precautions must be observed for other diseases with whose agents of infection we are not acquainted; as, for instance, yellow fever.

In view of the facility with which infectious germs derived from human beings or animals may gain access to the soil, it becomes a matter of great importance to determine how far such germs find in the soil conditions favorable for their preservation or their growth. We have, as is well known, a number of epidemiological observations bearing upon this subject, but with few exceptions these can be variously interpreted, and it is not my purpose to discuss them. The more exact bacteriological methods can, of course, be applied only to the comparatively small number of infectious diseases, the causative germs of which have been isolated and cultivated, and these methods hitherto have been applied to this question only imperfectly. We cannot regard the soil as a definite and unvarying substance in its chemical, physical, and biological properties. What has been found true of one kind of soil may not be so of another. Moreover, we cannot in our experiments, bring together all of the conditions in nature which may have a bearing on the behavior of spe-

cific micro-organisms in the soil. We must, therefore, be cautious in coming to positive conclusions on this point on the basis of experiments, especially those with negative result. With these cautions kept constantly in mind, the question, however, is one eminently open to experimental study.

The experiments which have thus far been made to determine the behavior of infectious micro-organisms in the ground have related especially to the bacilli of anthrax, of typhoid fever, and of cholera, and, fortunately, these are the diseases about whose relations to the ground there has been the most discussion and concerning which we are most eager to acquire definite information.

As regards anthrax bacilli, it has been determined that in ordinary garden or field earth they do not multiply, but in earth contaminated by blood, urine, or fæces their reproduction can occur. They can grow on various vegetable substrata. There is no reason to doubt, therefore, that the anthrax bacilli can find in or on the ground suitable conditions for their multiplication, although such conditions are not everywhere present. For durable infection of the soil with anthrax bacilli it is, however, more important that these bacilli should find there suitable conditions for the formation of spores than that they should be able simply to multiply. The vegetative forms of anthrax bacilli would not, as a rule, be able to survive for a great length of time the hostile influences which they are likely to encounter in the ground, such as insufficient or exhausted nutriment, absence of sufficient moisture, and the attacks of saprophytic organisms. On the other hand, against these injurious influences the anthrax spores have great resistance. In the superficial layers of the ground the anthrax bacilli may often find those conditions of moisture, of temperature, of oxygen supply, and of insufficient food which we know are most favorable for the development of their spores; indeed, Soyka has shown that the ground presents often these conditions better than our culture media. A circumstance discovered by Feltz, which, however, needs confirmation, is, if true, of not little significance. He finds that anthrax bacilli may undergo a progressive diminution in virulence in the soil. If this should be true likewise of other infectious micro-organisms, we should be able to account in some instances for the variable degree of virulence which clinical observation indicates that certain agents of infection acquire. So far as anthrax bacilli are concerned, we may conclude, therefore, that the ground occasionally offers suitable conditions for their reproduction, but what is of greater importance, it offers especially favorable conditions for their long-continued preservation in the form of spores. I must forego here the further consideration of the special circumstances inherent in the soil which control the origin and spread of epidemics of anthrax in cattle, although many interesting investigations have been directed to this subject.

Of greater interest to physicians is the behavior of typhoid and of cholera bacteria in the ground. As has already been intimated, the ground is regarded by Pettenkofer and his school as the principal breeding-place of these micro-organisms outside of the body. This view, however, is not supported by bacteriological investigations. Inasmuch as the cholera and typhoid bacilli may multiply on various vegetable substrata and substances derived from animals at temperatures often present in the ground, it is evident that here and there conditions may be present for their growth in the ground, but this growth is likely to be soon interrupted by the invasion of ordinary saprophytic organisms and other harmful influences. The typhoid bacilli are more hardy in resisting these invaders than are the cholera bacteria, which easily succumb, but even for the former, so far as our present knowledge extends, the ground can rarely serve as a favorable breeding-place.

It is not, however, necessary that these organisms should multiply in order to infect for a considerable time the ground; it is sufficient if their vitality is preserved. As to this latter point, the reports of different investigators are not altogether concordant. Such excellent observers as Koch, Kitasato, and Uffelmann found that the cholera bacteria, when added to fæces, or a mixture of fæces and urine, rapidly diminished in number, and at the end of three or four days, at the most, had wholly disappeared. In a mixture of the intestinal contents from a cholera corpse with earth and water, Koch found numerous cholera bacteria at the end of three days, but none at the end of five days. On the other hand, Gruber reports the detection of cholera bacteria in cholera dejecta fifteen days old. The weight of bacteriological evidence, therefore, is opposed to the supposition that the bacteria of Asiatic cholera preserve their vitality for any considerable time in the ground or in the excreta.

With respect to the bacilli which cause typhoid fever, it has been shown by Uffelmann that these may live in fæces, a mixture of fæces and urine, and a mixture of garden earth, fæces, and urine for at least four and five months, and doubtless longer, although they may die at the end of a shorter period. He also finds that under these apparently unfavorable conditions some multiplication of the bacilli may occur, although not to any considerable extent. Grancher and Deschamps found that typhoid bacilli may live in the soil for at least five months and a half. Unlike the cholera bacteria, therefore, the typhoid bacilli may exist for months at least in the ground and in fecal matter, holding their own against the growth of multitudes of saprophytes. This difference in the behavior of cholera and of typhoid germs is in harmony with clinical experience.

As regards other infectious bacteria than those which have been considered, I shall only mention that tubercle bacilli, although incapable of multiplication under the ordinary conditions of nature outside of the body, may preserve their vitality for a long period in the ground, on account of their resistant character, and, furthermore, that the pyogenic cocci, on account of their considerably resistant nature and their modest demands in the way of nutriment, can be preserved and sometimes probably grow in the ground. Indeed, the staphylococcus pyogenes aureus has been found in the earth by Lübbert.

The conclusion which we may draw from the observations mentioned is that, in general, the soil is not a good breeding-place for most of the infectious bacteria with which we are acquainted, but that it can retain for a long time with unimpaired vitality those which produce spores or which offer considerable resistance to injurious agencies, such as anthrax bacilli, typhoid bacilli, tubercle bacilli, and the pyogenic cocci.

In order to become infected with bacteria in or on the ground, these bacteria must in some way be introduced into the body, and we must, therefore, now attempt to determine how bacteria may be transported to us from the ground. So various and intricate are the possibilities for this transportation that it is hopeless to attempt to specify them all.

There occurs to us, first, the possibility of the conveyance of infectious micro-organisms from the soil by means of currents of air—a mode of carrying infection which has already been considered. Here I shall only repeat that the wind can remove bacteria from the ground only when the surface is dry and presents particles of dust, and that the sole, perhaps the chief, danger is not that we may inhale the infected dust.

Manifold are the ways in which we may be brought into contact with infectious bacteria in the ground, either directly or by means of vegetables to which particles of earth are attached, by the intervention of domestic animals, by the medium of flies or other insects, and in a variety of other ways, more or less apparent.

An important, doubtless for some diseases the most important, medium of transportation of bacteria from an infected soil is the water which we drink or use for domestic purposes. From what has been said, it is evidently not the subsoil water which is dangerous, for

infectious, like other bacteria, cannot generally reach this in a living state, but the danger is from the surface-water, and from that which trickles through the upper layers of the ground, as well as from that which escapes from defective drains, gutters, cesspools, privy-vaults, and wrongly constructed sewers or improper disposal of sewage. I shall have something to say presently of water as a source of infection, and shall not further elaborate here the dangers of infection of drinking-water through contaminated soil; dangers which, especially as regards typhoid fever, are widely appreciated in this country, even if often imperfectly counteracted.

A point which has been much discussed, and one of interest, is whether bacteria which are in the depth of the ground can come to the surface. Two agencies, especially, have been considered by some as capable of transporting bacteria from the depth to the surface. One is ascending currents of air in the ground, and the other is the capillarity of fluids in the minute pores of tne ground. The first of these suspected agencies must be unquestionably rejected, in view of the fact that even a few inches of sand is sufficient to filter all of the bacteria out of the air, even when it is in much more rapid motion than can occur within the ground. Moreover, that degree of dryness which is essential for the detachment of bacteria by air-currents is not likely to be present much below the surface of the ground. The experiments which have been made to determine to what extent bacteria may be carried upward by the capillarity of fluids in the ground have not yielded harmonious results, but the weight of evidence is opposed to the belief that this is a factor of any considerable importance for this purpose.

From what has been said concerning the growth of pathogenic bacteria in the soil, we shall not be inclined to attribute to the multiplication and the motility of these organisms much influence in changing their place in the ground.

The somewhat sensational rôle assigned by Pasteur to earthworms, of bringing bacteria to the surface, cannot be wholly ignored, and has received support from observations of Bollinger regarding anthrax, but it is questionable whether much importance is to be attached to this agency.

Regarding the depth to which typhoid bacilli may penetrate in the soil, the experiments of Grancher and Deschamps show that at the end of five weeks they may reach a depth of sixteen to twenty inches below the surface. As Hoffmann has demonstrated the extraordinary slowness with which fluids and fine particles penetrate the soil, it is probable that in the course of time a greater depth than this may be reached. Indeed, Macé claims to have found in the neighborhood of a well, suspected of infection, typhoid bacilli, together with ordinary intestinal bacteria, at a depth of at least six and a half feet below the surface. There are a number of instances recorded in which there is good reason to believe that turning up the soil, and cleaning out privies or dung-heaps in which typhoid stools have been thrown, have given rise to typhoid fever, even after the infectious excreta have remained there a year and more.

It cannot be said that bacteriological investigations have as yet shed much light upon a factor which plays a great rôle in epidemiology, namely, predisposition to infection from the ground, according to locality and time, and this deficiency receives constant and vehement emphasis from the localistic school of epidemiologists. We can, however, readily understand that varying conditions, such as temperature, moisture, porosity, quality of soil, may exert a controlling influence in determining the behavior of infectious germs in the soil, and the facility of their transportation to human beings or animals. As regards that much discussed question, the significance of variations in the height of the subsoil-water, in relation to the prevalence of cetain epidemic diseases, particularly cholera and typhoid fever, we now know that this cannot depend upon the presence of bacteria in the subsoil-water itself, or in the capillary layers immediately above it. It has been plausibly suggested that with the sinking of the subsoil-water fluids from infected cesspools, privy-vaults, and other localities may more readily be drawn into wells or other sources of water-supply, and that by the same cause the surface of the ground becomes dry, so that dust-particles may be lifted by the wind. Other more or less plausible explanations have also been offered, but it must be confessed that our positive information on this point is meagre. There can, however, be little doubt that this significance of the variations in subsoil-water is apparent only for certain localities, and has been considerably exaggerated and often misunderstood. It is not, however, pertinent to my theme to discuss this or other purely epidemiological observations concering the relations of the ground to the spread of epidemic diseases, interesting and important as are many of these observations.

Before leaving the subject of the ground as a source of infection, permit me to indicate briefly some conclusions which may be drawn from what has been said, as to the principles which should guide us in preventing infection, directly or indirectly, from the ground.

First in importance is to keep infectious substances as far as possible from the ground. This implies the early disinfection or destruction of such substances as typhoid and cholera excreta and tuberculous sputum.

Second, the ground should be rendered, so far as practicable, unsuitable for the continued existence of infectious germs. This, at least for some diseases, is accomplished by a proper system of drainage, which, moreover, for other reasons, possesses hygienic importance.

Third, means should be provided to prevent waste products from getting into the ground around human habitations, or from gaining access to water used for drinking or domestic purposes. In cities this can be accomplished only by a properly constructed system of sewers. The system of storing waste products in cesspools, whence they are to be occasionally removed, cannot be approved on hygienic grounds. There are conditions in which the disposal of waste products in deep wells only used for this purpose, and whence these products can filter into the deep layers of the ground, may be permissible, but this can never be considered an ideal method of getting rid of excrementitious substances, and is wholly wrong in regions where wells are used for drinking-water. But I am trespassing with these remarks upon a province which does not belong to me, but rather to practical sanitarians and engineers. I shall only add that the advantage gained by preventing organic waste from soaking into the ground is not so much that the ground is thereby rendered better adapted for the existence of infectious micro-organisms, but is due rather to the fact that this waste is likely to contain infectious germs.

Finally, in cities, good pavements, absence of unnecessary disturbance of the soil, cleanliness of the streets, and laying of dust by sprinkling are not only conducive to comfort but are sometimes hygienically important in preventing infection from the ground and dust.

In passing from the consideration of the ground to that of water, one feels that he now has to do with a possible source of infection against which, in this country and in England, he is at liberty to make any accusation he chooses without fear of contradiction. There is reason to believe that such accusation has been repeatedly made, without any proof of misdemeanor on the part of the water. It is not, therefore, with any desire to awaken further the medical or the public conscience that I wish to say a few words concerning the behavior of bacteria in water, and the dangers of infection from this source. That such dangers are very real must be apparent when we consider the universal employment of water, and its exposure to contamination from all kinds of sources.

Ordinary water, as is well known, contains bacteria in large number. Not a few species of bacteria can multiply rapidly, and to a large amount, even in distilled water. These are the so-called water-bacteria, and, like most of

the micro-organisms found in ordinary drinking-water, are perfectly harmless saprophytes. What we wish to know is, how pathogenic micro-organisms conduct themselves in water. Can they grow, or be preserved for any length of time in a living condition in water? As regards the multiplication of pathogenic bacteria in water, the results of different experimenters do not altogether agree. Whereas Bolton failed to find any growth, but rather a progressive diminution, in number of pathogenic bacteria planted in sterilized water, Wolffhügel and Riedel observed a limited reproduction of such bacteria, including those of typhoid fever and of cholera. This difference is due probably to the methods of experimentation employed. According to Kraus, these latter bacteria diminish rapidly in number in unsterilized spring or well water kept at a low temperature. These experiments indicate that water, even when contaminated with more organic impurities than are likely ever to be present in drinking-water, is not a favorable breeding-place for pathogenic bacteria. Still it is to be remembered that these laboratory experiments do not reproduce exactly all of the conditions in nature, and it may happen that in some nook or cranny, or vegetable deposit at the side of a well or stream, some pathogenic bacteria may find suitable conditions for their multiplication.

But, as has been repeatedly emphasized in this address, it is not necessary that pathogenic bacteria should actually multiply in a medium in order to render it infectious. It is sufficient if their life and virulence are not destroyed in a very short time. As to this important point Bolton found that in sterilized water typhoid bacilli may preserve their vitality for over three months, and cholera bacteria for eight to fourteen days, while Wolffhügel and Riedel preserved the latter in water for about eighty days. Under natural conditions, however, these organisms are exposed to the overgrowth of the water bacteria, so that Kraus found in unsterilized water kept at a temperature of 10.5° C. the typhoid bacilli no longer demonstrable after seven days, and the cholera bacteria after two days. The conditions in Kraus' experiments were as unfavorable as possible for the continued existence of these pathogenic bacteria, more unfavorable than those often present at the season of prevalence of cholera and typhoid fever; nevertheless I do not see that they justify the conclusions of Kraus as to the slight probability of drinking-water ever conveying infection with the germs of typhoid fever and of cholera. To render such a conclusion probable it would be necessary to demonstrate a much shorter preservation than even Kraus himself found. In judging this question it should not be overlooked that infection of drinking-water with the typhoid or the cholera germs is not so often the result of throwing typhoid or cholera stools directly into the source of water-supply as it is the consequence of leaky drains, cesspools, privy-vaults, or infected soil, so that there may be continued or repeated accessions of infected material to the water.

In view of the facts presented, there is no sufficient reason, therefore, from a bacteriological point of view, of rejecting the transmissibility of typhoid fever and cholera by the medium of the drinking-water. This conclusion seems irresistible when we call to mind that Koch once found the cholera bacteria in large numbers in the water of a tank of India, and that the typhoid bacilli had been repeatedly found in drinking-water of localities where typhoid fever existed. Nor do I see how it is possible to interpret certain epidemiological facts in any other way than by assuming that these diseases can be contracted from infected drinking-water, although I know that there are still high authorities who obstinately refuse to accept this interpretation of the facts.

In this connection it may be mentioned that pathogenic bacteria may preserve their vitality longer in ice than in unsterilized drinking-water. Thus Prudden found typhoid bacilli still alive which had been contained in ice for one hundred and three days.

When we come to consider the ways in which water may become infected with pathogenic micro-organisms we recognize at once a distinction in this respect between surface-water and subsoil-water. Whereas the subsoil-water may be regarded under ordinary circumstances and in most places as germ-free, the surface-water, such as that in rivers and streams, is exposed to all manner of infection from the ground, the air, and the direct admission of waste substances. Unfortunately, in the ordinary way of obtaining subsoil-water for drinking purposes by means of dug wells, this distinction is obliterated, for the water which enters these wells free from bacteria is converted into a surface-water often exposed, by the situation of the well, to more dangerous contamination than other surface-waters used for drinking purposes.

Now let us turn our attention, as we have done with other sources of infection, to a brief outline of certain general principles which may help us in avoiding infection from the water.

We shall, in the first place, avoid, so far as possible, the use of water suspected of infection, especially with the germs of such diseases as typhoid fever and cholera. When it is necessary to use this suspected water it should be boiled.

As regards the vital question of water-supply, it may be stated as a general principle that no hygienic guarantee can be given for the purity of surface-water which has not been subjected to a proper system of filtration, or for the purity of spring- or well-water fed from the subsoil, unless such water is protected from the possibility of infection through the upper layers of the soil or from the air. This is not saying that water which meets certain chemical and biological tests, and which is so situated that the opportunities for its contamination appear to be absent or reduced to a minimum, is not admissible for the supply of drinking-water, but the possibility of infection can be removed only by the fulfilment of the conditions just named, and upon these conditions the hygienic purist will always insist.

Unfortunately we have at present no domestic filters which are satisfactory, and most of those in common use are worse than none, as they soon furnish a filtrate richer in bacteria than the original water. The only effective method of water-filtration for the general supply is by means of large sand-filters, such as are in use with excellent results in Berlin and some other cities. These require skilled attention. I cannot on this occasion discuss the construction or working of these filters, but would refer those who are interested to the full and careful investigations of the Berlin filters by Wolffhügel, and by Plagge, and Proskauer.

What is accomplished by these artificial sand-filters is accomplished under natural conditions also by the ground, which furnishes a subsoil-water free from micro-organisms, and to obtain pure water we have only to devise means by which this subsoil-water may be secured without the chance of contamination. Just as the water which has passed through the sand-filters is collected in suitable reservoirs and is distributed in pipes which do not admit contamination from without, so by means of properly constructed artesian or driven wells we may secure the naturally filtered subsoil-water with the same freedom from the chances of infection.

It is well to bear in mind that no biological or chemical tests of water can replace those measures which have been mentioned as necessary to secure purity of water-supply. These tests are of value only when applied with proper precautions and with due consideration of the special circumstances of each case for which they are employed. There has been much profitless discussion as to whether greater significance is to be attached to the chemical or to the bacteriological examination of water. Each has its own special field of application, and in this the one cannot replace the other method. The bacteriological examination has for hygienic purposes the advantage that it may enable us to detect the specific agents of infection in the form of micro-organisms, as has already been done

for cholera bacteria and typhoid bacilli, but this is a comparatively rare result and does not at present afford a wide field of application for this method. The significance of the bacteriological test is to be based more frequently upon the fact that it concerns itself with the same class of micro-organisms to which some of the recognized, and, doubtless, many of the undiscovered, infectious agents belong, and from the behavior of which, in some respects, conclusions can be drawn as to the behavior of the pathogenic organisms. Thus the bacteriological test is the only one which enables us to judge correctly of the efficacy of those methods of filtration of surface-water and of construction of wells which insure purity of water-supply. The points of view from which we can estimate correctly, according to our present knowledge, the relative merits and fields of application of the chemical and of the bacteriological methods of water-examination have been clearly indicated by Plagge and Proskauer and by Wolffhügel. The theme is one beyond the limits or the scope of this discourse, and I have referred to it chiefly to emphasize the fact that we cannot rely upon chemical or bacteriological tests of water to the exclusion of those protective measures which have been mentioned, although I do not intend to imply that each of these tests, when properly employed, does not afford important information and is not of great value in many cases.

I have already taxed so largely your time and patience that I must pass over with brief mention the food as a source of infection. Unlike those external sources of infection which we have hitherto considered, many articles of food afford an excellent nutritive medium for the growth of a number of species of pathogenic micro-organisms, and in many instances this growth may be abundant without appreciable change in the appearance or taste of the food.

When we consider in how large a degree the certainty and the severity of infection with many kinds of pathogenic micro-organisms depend upon the number of such organisms received into the body, we can appreciate that the danger of infection from food which contains a mass of growing pathogenic bacteria may be much greater than that resulting from the reception of infected water or air, media in which infectious organisms are rarely present in other than a very dilute condition. The entrance into the body of a single infectious bacterium with the inspired air is, at least in the case of many diseases, not likely to cause infection; but let this bacterium fall upon some article of food, as, for instance, milk, where it can multiply in a short time at a favorable temperature many thousand-fold, and evidently the chances of infection become vastly increased.

Among the various agencies by which infectious organisms may gain access to the food may be mentioned the deposition of dust conveyed by the air, earth adhering to vegetables, water used in mixing with or in the preparation of food, in cleansing dishes, cloths, etc., and contact in manifold other ways with infected substances.

Fortunately a very large part of our food is sterilized in the process of cooking shortly before it is partaken, so that the danger of infection from this source is greatly diminished, and comes into consideration only for uncooked or partly cooked food, and for food which, although it may have been thoroughly sterilized by heat, is allowed to stand for some time before it is used. Milk, in consequence of its extensive use in an unsterilized state, and of the excellent nutritive conditions which it presents to many pathogenic bacteria, should be emphasized as especially liable to convey certain kinds of infection, a fact supported not less by bacteriological than by clinical observations. Hesse found that also a large number of ordinary articles of food, prepared in the kitchen in the usual way for the table, and then sterilized, afford a good medium for the growth and preservation of typhoid and cholera bacteria, frequently without appreciable change in the appearance of the food.

Upon solid articles of food bacteria may multiply in separate colonies, so that it may readily happen that only one or two of those who partake of the food eat the infected part, whereas with infected liquids, such as milk, the infection is more likely to be transmitted to a larger number of those who are exposed.

In another important particular the food differs from the other sources of infection which we have considered. Not only the growth of infectious bacteria, but also that of bacteria incapable of multiplication within the body may give rise in milk and other kinds of food to various ptomaïnes, products of fermentation, and other injurious substances, which, when ingested, are likely to cause more or less severe intoxication, or to render the alimentary tract more susceptible to the invasion and multiplication of genuinely infectious organisms.

It is plain that the liability to infection from food will vary according to locality and season. In some places and among some races the proportion of uncooked food used is much greater than in other places and among other races. In general, in summer and in autumn the quantity of fruit and food ingested in the raw state is greater than at other seasons, and during the summer and autumn there is also greater danger from the transportation of disease-germs from the ground in the form of dust, and the amount of liquids imbibed is greater. The elements of predisposition, according to place and time, upon which epidemiologists are so fond of laying stress, are not, therefore, absent from the source of infection now under consideration.

I have thus far spoken only of the secondary infection of food by pathogenic micro-organisms, but, as is well known, the substances used for food may be primarily infected. Chief in importance in the latter category are the various entozoa and other parasites which infest animals slaughtered for food. The dangers to mankind resulting from the diseases of animals form a separate theme, which would require more time and space than this address affords for their proper consideration. I shall content myself on this occasion with only a brief reference to infection from the milk and flesh of tuberculous cattle.

It has been abundantly demonstrated by numerous experiments that the milk from tuberculous cows is capable, when ingested, of causing tuberculosis. How serious is this danger may be seen from the statistics of Bollinger, who found with cows affected with extensive tuberculosis the milk infectious in eighty per cent. of the cases; in cows with moderate tuberculosis the milk infectious in sixty-six per cent. of the cases; and in cows with slight tuberculosis the milk infectious in thirty-three per cent. of the cases. Dilution of the infected milk with other milk, or with water, diminished, or, in sufficient degree, it removed the danger of infection. Bollinger estimates that at least five per cent. of the cows are tuberculous. From statistics furnished me by Mr. A. W. Clement, V.S., it appears that the number of tuberculous cows in Baltimore which are slaughtered is not less than three to four per cent. Among some breeds of cattle tuberculosis is known to be much more prevalent than this.

There is no evidence that the meat of tuberculous cattle contains tubercle bacilli in sufficient number to convey infection, unless it be very exceptionally. Nevertheless one will not willingly consume meat from an animal known to be tuberculous. This instinctive repugnance, as well as the possibility of post-mortem infection of the meat in dressing the animal, seem to be good ground for discarding such meat. The question, however, as to the rejection of meat of tuberculous animals has important economic bearings and has not been entirely settled. As to the rejection of the milk from such animals, however, there can be no difference of opinion, although this is a point not easily controlled.

The practical measures to adopt in order to avoid infection from the food are, for the most part, sufficiently obvious. Still, it is not to be expected that every possibility of infection from this source will be avoided. It is

difficult to discuss the matters considered in this address without seeming to pose as an alarmist. But it is the superficial and half knowledge of these subjects which is most likely to exaggerate the dangers. While one will not under ordinary circumstances refrain from eating raw fruit or food which has not been thoroughly sterilized, or from using unboiled or natural waters in the fear that he may swallow typhoid or cholera bacteria, still, in a locality infected with cholera or typhoid fever, he will, if wise, not allow himself the same freedom in these respects. Cow's milk, unless its source can be carefully controlled, should, when used as an habitual article of diet, as with infants, be boiled, or the mixed milk of a number of cows should be selected; but this latter precaution offers less protection than the former.

In most places in this country we are sadly lacking in good sanitary inspection of the food, especially of the animal food, offered for sale. One cannot visit the slaughter-house in Berlin or in Munich, and doubtless similar ones are to be found elsewhere, and watch the intelligent and skilled inspection of the slaughtered animals without being impressed with our deficiency in this respect. In large cities an essential condition for the efficient sanitary inspection of animal food is that there should be only a few places, and preferably only one place, where animals are permitted to be slaughtered. Skilled veterinarians should be selected for much of the work of inspection.

It may reasonably be asked that the National government, which has already spent so much money for the extermination of such diseases as pleuro-pneumonia of cattle and hog cholera, which are not known to endanger the health of mankind, should turn its energies also to means for eradicating tuberculosis from cattle, which is a scourge not only to the economic interests of farmers and dairymen, but also to the health of human beings.

Without any pretension to having done more in this address than to sketch here and there a few principles derived from bacteriological researches concerning only some of the most widely distributed external sources of infection, I trust that enough has been said to show the folly of any exclusive dogma as to modes of infection. The ways of infection even in one and the same disease are manifold and various, and can never be resolved into exclusive hypotheses, such as the drinking-water hypothesis, the ground hypothesis, etc.

It follows, therefore, that it is not by sanitary improvements in one direction only that we can control the spread of preventable epidemic diseases. In one situation improvements in the supply of drinking-water check the prevalence of typhoid fever, in another place similar measures show no such influence; or again, in one city the introduction of a good system of sewerage diminishes epidemic diseases, and in another no similar result follows. We should, therefore, aim to secure, as far as possible, good sanitary arrangements in all directions and in all respects.

It has also been rendered evident in what has been said, that infectious agents differ markedly from each other in their behavior, so that while public sanitation aims at those measures which are found to be most widely beneficial, it should not forget that each infectious disease is as much a separate problem in its prophylaxis as in its symptomatology, etiology, and treatment. It will not aim to combat cholera with the means found best adapted to scarlet fever, but it will adapt preventive measures as directly to the specific end in view as possible. In presenting to you the results of researches chiefly bacteriological concerning the scientific basis of preventive medicine, I hope to escape the accusation of one-sidedness and narrowness by the statement that I do not for a moment intend to imply that the bacteriological method is our only source of accurate knowledge on the subjects which have been considered. My aim is accomplished if I have succeeded in making clear that this method has established facts which aid in a clearer conception of the causes of some important infectious diseases, in a better understanding of the sources and dangers of infection, and in a more efficient selection and application of sanitary measures.

If this science of only a few years' growth has furnished already acquisitions to knowledge so important, so far reaching, may we not look forward with assurance to the solution of many dark problems in the domain of infectious diseases—problems the solution of which may yield to preventive medicine a future of usefulness and success which we cannot now foresee?

## A CLINICAL STUDY OF SOME ANTISEPTICS IN THE TREATMENT OF OTORRHŒA.[1]

By ROBERT L. RANDOLPH, M.D.,

PATHOLOGIST AND ASSISTANT SURGEON TO THE PRESBYTERIAN EYE AND EAR CHARITY HOSPITAL, BALTIMORE, MD.

In considering the treatment of inflammations of the middle ear by means of antiseptic agents, it is desirable to call to mind the distinction between the prophylactic and the curative uses of antiseptic applications. We employ prophylactic antisepsis in order to prevent the entrance of micro-organisms into wounds, while by means of curative antisepsis we endeavor to render aseptic wounded or diseased areas in which micro-organisms have already secured lodgement.

The anatomical structure of the ear renders comparatively narrow the field of application of antiseptics for prophylactic purposes. In operations and wounds involving the tragus, helix, and the periosteum of the mastoid process, antisepsis can be employed with prophylactic effect. Indeed, in operations in the external auditory canal we may hope for the same effect, although here, for manifest reasons, it is more difficult to secure and retain a perfectly aseptic condition. If there be perforation of the drum membrane, the possibility of keeping the organ completely free of germs is practically out of the question, for the connection between the tympanic cavity and the throat—namely, through the Eustachian tubes—is always a way open for the bacteria which pass into the mouth with every inhalation and with every mouthful of food.

From the anatomical structure of the ear, then, comparatively little is to be expected from the employment of antisepsis as a prophylactic. As a curative agent it does admirable work.

There are two ways by which an antiseptic fluid may reach the middle ear. First, by way of the external auditory canal through a perforation of the drum-membrane; and second, through the Eustachian tube. Through this latter channel the fluid can reach the middle ear, but owing to the small opening and the difficulty of its access the operation becomes tedious and frequently impracticable. And furthermore, there is necessarily a good deal of the liquid swallowed by the patient. Now, some of our most valuable antiseptics, when taken internally, even in small doses, produce toxic symptoms. The external ear, then, is the safest and simplest road to the middle ear.

It is not surprising, in cases of obstinate suppurative inflammations of the middle ear, that these affections do not yield promptly to treatment, for the different parts of this division of the ear are singularly difficult of access. The middle ear is simply a series of channels, spaces which are divided and subdivided into an infinite number of smaller spaces. The drum-cavity, the centre, with its irregular and angular walls, is the point from which ramify the divisions of the middle ear. Here are numerous pockets where a discharge can rest and engender organisms. On the posterior wall there is the opening into the antrum mastoideum, or horizontal portion of the mastoid process, another point where secretions can accumulate. From thence we pass on into the mastoid process itself, where are located the mastoid cells. Here we have an array of pockets, chambers, recesses in which micro-organisms

[1] Read before the Clinical Society of Baltimore, February 1, 1889.

can secure lodgement. It is thus evident how difficult, nay, almost impossible, it is to obtain an antiseptic condition of the middle ear.

After these preliminary considerations concerning the general uses of antiseptics, and the difficulties inherent in the anatomical structure of the ear regarding their application, I will now mention the antiseptics which I have employed during the past fifteen months in treating suppurative processes of the ear.

Carbolic acid gave most indifferent results. A disadvantage peculiar to carbolic acid is its tendency, says Kretschmann,[1] in a one per cent. solution, to produce eczema and otitis externa, accompanied with great pain. I cannot say that my experience entirely confirms this statement, but what I have seen of its action in otorrhœa has convinced me that it is, comparatively speaking, an inferior agent. Koch's investigations show that the spores of the anthrax bacillus, when exposed to a one per cent. solution of carbolic acid, are not destroyed. Only after exposure for twenty-four hours to a five per cent. solution is their activity destroyed. The pus micro-organisms, however, are much less resistant than the spores of anthrax bacilli, so that we cannot reject the use of carbolic acid in the treatment of most cases of suppurative otorrhœa simply on the ground of its inferior antiseptic powers; but its irritating properties, as cited by Kretschmann, form a positive objection to its employment. Moreover, it has not yielded in my hands so satisfactory curative results as some other agents.

As regards iodoform, though I have used it in several cases, I must confess I have not given it an extended trial. Very few patients in private practice will tolerate its presence, particularly in the ear, where, from the exposed position of the organ, it is more difficult to suppress the odor. This objection I have found a not infrequent one, even among the better class of dispensary patients. In those cases where I used it the patients were undoubtedly benefited, for the discharge was clearly lessened by daily applications of the powder. The question as to the antiseptic value of iodoform is such a vexed one, and laboratory experiments and clinical experience differ here so widely, that I will not attempt a discussion of the subject from this point of view. It is claimed that iodoform owes most, if not all, of its antiseptic value to its property of destroying ptomaïnes. For an interesting survey of the present status of the iodoform question, I would refer to a recent article in the *Annals of Surgery*[2] by William W. Van Arsdale, M.D.

In 1880 Bezold advised the use of finely pulverized boracic acid for acute and chronic suppurating diseases of the drum-cavity with perforation. This agent is recommended mainly for its value as an antiseptic. It is supposed to act not only by disinfecting the secretion, but also by preserving an aseptic condition of the mucous membrane. Again, it is urged that its freedom from irritating qualities permits its use with perfect impunity by laity and physician alike. And, finally, the persevering use of boracic acid is claimed, with few exceptions, to cure every discharge from the ear. Such promises naturally provoked an unqualified use of this agent, but it was not long before reports appeared which showed that boracic acid fell far short of doing in every case what was expected of it; that there were limitations to its use, certain kinds of cases where it was indicated, others where it did absolutely no good, others again where it was positively dangerous.

Professor Schwartze, of Halle, in his treatise, "Die Chirurgischen Krankheiten des Ohres," says that in certain cases of chronic otorrhœa, boracic acid, when introduced in small quantities into the ear, will effect a cure. Such cases are those in which the perforation is large and situated in the lower quadrant of the drum-membrane, and in which the secretion is not very abundant. He advises against the use of boracic acid when the secretion is very abundant and thick, for here a sticky mass will be formed which adheres to the walls of the cavity and stops up and prevents the egress of the discharge, and which sometimes results in retention of pus, inflammation of the mucous membrane covering the bones, and, finally, of the bones themselves. Schwartze thinks that the use of boracic acid is contra-indicated in acute otorrhœa of the drum-cavity. Here we have a thick muco-purulent discharge, and generally a very small perforation, and just such a condition may arise as described above, namely, retention and all its unfortunate consequences.

Dr. Stacke,[1] in an article on the subject, mentions a case of chronic otorrhœa with medium-sized perforation, situated on the upper portion of the drum-membrane. Inasmuch as the mucous membrane seemed pale and smooth and the discharge was slight, only a small quantity of powder was blown into the ear. After four weeks, during which period he had not seen the patient, the latter came back for an examination. There had been no discharge for some time. The drum-membrane was coated with a fine adherent scale, and, on using the Politzer bag, a moist râle was heard. A closer examination revealed a drum-cavity full of pus. In this case there existed a condition unfavorable for the free exit of the discharge, the slight secretion in the beginning had formed over the perforation a thin scale which, with time, became stronger and more resistant, and when the secretion increased in quantity, the scale which covered the perforation was too strong to give way, and hence retention followed. Timely discovery prevented dangerous consequences. In two cases he observed brain-symptoms after three weeks' use of the powder. Stacke mentions four other cases of chronic otorrhœa, which he had treated for a long time with boracic acid. In all four cases the discharge was brought to a standstill, but suppuration continued, and before he obtained complete recovery he was obliged in two cases to trephine the mastoid, and in the other two, excise the malleus.

Dr. Grüning,[2] of New York, reports three cases of death from retention of pus after a long use of boracic acid in the powder form. In the course of the disease nothing unusual was observed in either case, till after they had been for some time under the boracic-acid treatment. Two cases died of meningitis, and the other one of pyæmia. In one of the cases the mastoid process was opened the day before death, and it was found full of pus.

I have not met with such unfortunate results in my experience with boracic acid, although entire paralysis of one side of the face occurred in a child that had been seen by me not long ago, and which condition might readily be attributed to having packed the external ear with the powder. The case was that of a child aged eight years, that had been troubled with a persistent otorrhœa for three years. An examination showed that the entire drum-membrane was gone, and that the tympanic cavity was full of granulations. I touched the latter with chromic acid and prescribed an acid sublimate solution, to be poured into the ear three times daily, and to remain in the ear five or ten minutes at a time. I heard nothing more of the patient for a month, when I received a letter from the family physician stating that the child was paralyzed on the left side of the face. For the first three or four days after using the sublimate solution the discharge, from having been copious, had lessened to a few drops a day, and the fetor had entirely disappeared. The doctor said that, not being able to stop the discharge completely, he thought he would pack the ear with powdered boracic acid. This was done, and ten days later he noticed the facial palsy. Facial paralysis as a result of otitis media is

[1] Archiv für Ohrenheilkunde, Bd. xxvi., S. 109.

[2] Three Fatal Cases of Middle-ear Suppuration after Treatment with Boric-acid Powder. Transactions of the American Otological Society Vol. iv., Part i., 1887.

not a very rare occurrence, and it is quite possible that, even had the boracic acid not been used, the paralysis would have shown itself sooner or later. In this case, however, the disease for three years had been marked by no unusual symptoms, and for two weeks was so improved by a certain line of treatment that the otorrhœa had nearly ceased, and the accompanying odor had entirely disappeared. A new treatment was then adopted, and a few days later the case presented a more unfavorable outlook than at any time during the three years. It is quite fair to conclude that the powder offered a mechanical obstruction to the small discharge that was still going on, and that this latter, accumulating in the bottom of the cavity, produced pressure upon the chorda tympani and hence paralysis, or, possibly, an actual extension of the inflammation to the nerve itself ensued. This is the only instance in my experience when the use of boric acid was attended with unfortunate consequences. Both in the powder form and in solution this agent has done me good service, and many persistent otorrhœas have been permanently cured.

I have found no agent, however, which has yielded such good results as the bichloride of mercury. I use it in solutions varying in strength from 1 to 3,000 to 1 to 8,000 and 10,000.

Koch's investigations show that the spores of the anthrax bacillus are rendered perfectly innocuous after a few minutes' immersion in a 1 to 20,000 sublimate solution. In experiments made with a sublimate solution of 1 to 1,000 the following organisms were destroyed in eight seconds: Anthrax bacilli (free from spores); the bacilli of diphtheria, glanders, and typhoid fever; streptococci from puerperal fever and from pus, the staphylococcus aureus and albus, and the organism of erysipelas. A solution of such strength is, of course, much too strong for the ear. The strongest solution that I have ever used is 1 to 3,000, and even this has caused pain when poured into the ear. The strength of the solution that I generally use is 1 to 5,000, and with this I have never had any complaints from the patients. It is well known that when a sublimate solution comes in contact with a substance containing albumen that a precipitate is thrown down which is usually regarded as the albuminate of mercury. This reaction is supposed to take place when we pour such a solution into an ear from which there is a purulent discharge, and here I would allude to the contradictory experiments of Drs. Laplace[1] and Behring.[2] The first of these investigators proved that when the albuminate of mercury is precipitated that the sublimate solution has lost much of its germicidal property. The same investigator has shown that this precipitate may be prevented by making the sublimate solution slightly acid. This solution, Dr. Laplace says, has lost none of its antiseptic value by the addition of the acid; on the contrary, it is a more powerful germicide than ever. Either tartaric or muriatic acid was used. According to Dr. Behring, this albuminate of mercury does not exist, or, rather, does not in the slightest degree resemble the insoluble albuminous coagulum produced by acids or heat. The so-called albuminate of mercury redissolves easily in acids, in iodide of potash, cyanide of mercury; in short, in all bodies which have the property of redissolving precipitates of mercury obtained in an aqueous solution. Furthermore, one can obtain from the serum of blood containing sublimate, dissolved by means of tartaric acid, the same reactions as those which an aqueous solution of sublimate will give. Again, all the reagents capable of dissolving the chloride of silver, as ammonia and cyanide of potash, are equally capable of preventing chloride of silver from producing a precipitate in blood-serum, and are capable of dissolving such a precipitate when it does occur, all of which goes to prove that the salts which are present in the blood play an important part in the existence of metallic precipitates, and that the albumen found in the precipitate is, so to speak, carried along mechanically. Dr. Behring further finds that the acid sublimate solution is a quarter less active as a germicide than the non-acidulated sublimate solution.

So much, then, for the question as viewed from the light of laboratory experiments. Clinical experience is not yet so divided, and I am every day, as surgeon in charge of a large ear clinic, together with frequent confirmations from my colleagues—being convinced of the positive good effected by the acid sublimate solution.

The following is the prescription used:

℞. Hydrarg. bichlor..... gr. ss.
Acid. tartar..... grs. xx.
Aquæ.....q. s. ad ℥ v.

The patient is first required to syringe the ear out with warm water, and then to pour the sublimate solution into the ear till the latter is quite full. The fluid is allowed to run out after remaining in the ear ten or fifteen minutes. A piece of cotton is then moistened with the solution, and with it the external opening of the ear is closed. This treatment is repeated two or three times a day. As far as possible, then, the tissues of the drum-cavity, its remote connections, and the whole external auditory canal are kept in a condition unfavorable for the growth of organisms. A marked diminution in the discharge is seen almost immediately, and not infrequently a patient will remark upon the absence of odor after the first day's applications. In granulations and in polypi sublimate solutions have only the effect of removing the fetor; the discharge is not lessened to any extent. Such conditions demand special treatment. But in the ordinary otorrhœa resulting from otitis media, which affection forms so large a percentage of the dispensary patients, the acid sublimate solution has given me most satisfying results. About seventy-five cases have been collected by me during the past year; but, unfortunately, I have not been able to follow up more than forty to the point of complete recovery.

As regards relapses, since I began treating the majority of suppurating diseases of the ear with an acid sublimate solution, I think I can safely say that the good done here has been no less permanent than when the majority of cases were treated with boracic acid or other agents. I may say that the greater part of the time a similar case was always kept on the boric-acid treatment, to judge of its relative merits, and in by far the majority of cases the improvement was quicker when the sublimate solution was used. Certainly the fetor disappeared more promptly when the latter agent was employed. The following cases may be regarded as fairly typical of the efficacy of this mode of treatment:

Case I.—C. K——, thirteen years of age. Chronic otitis media. Medium-sized perforation. Otorrhœa for two years. Treated with insufflations of boric acid for two weeks with no visible improvement. Commenced to use the sublimate solution, and the discharge had stopped on the eighth day. The perforation had become smaller, and subsequently healed over entirely.

Case II.—F. O——, thirty-three years of age. Chronic otitis media. Otorrhœa twelve years. Drum-membrane nearly gone. No sign of discharge on the tenth day. The patient was seen for three or four days after this, and as the otorrhœa had not returned he was discharged, with the injunction to come back if he had any further trouble. It is now at least six months since he was last seen.

Case III.—P. K——, eight years of age. Otitis media. Otorrhœa six weeks. Small perforation in upper and anterior quadrant of drum-membrane. The ear stopped discharging after using the sublimate solution for four days. As usual, the patient was kept under observation for several days after the discharge had ceased, at the end of which time he was allowed to go, and he has not been seen since.

[1] Säure Sublimatlösung als desinficirendes Mittel und ihre Verwendung in Verbandstoffen, Deutsche Med. Wochenschr., No. 40, S. 866, 1887.

[2] Ueber Quecksilbersublimat in eiweisshaltigen Flüssigkeiten, Centralblatt für Bakteriologie u. Parasitenkunde, 2. Jahrgang, Bd. iii., Hft. 1, 2.

CASE IV.—J. B——, five years of age. Acute suppuration of the middle ear. Small perforation and otorrhœa for one week. There was no sign of the discharge on the tenth day.

CASE V.—Mrs. R——, fifty years of age. Chronic inflammation of the middle ear. Large perforation and otorrhœa for four months. The discharge stopped on the seventh day. There was no closing up of the perforation though the ear remained free of any discharge, and the patient was allowed to go after having been about two weeks under observation.

CASE VI.—A. W——, two months old. Otorrhœa first noticed about ten days after birth, and, furthermore, in both ears. In eight days the discharge from both ears had ceased.

Unfailing success was claimed by the author of the boric-acid treatment, but the experience of many aural surgeons has not borne out the truth of this promise. Certainly no such claim can be made for the sublimate solution. To succeed always is the lot of no drug. Some cases get well with no other treatment than syringing out the ear with warm water several times daily. This, however, is the exception. It will be observed that four days was the quickest period of time in which the discharge was stopped by the sublimate solution. I once stopped the discharge from an ear with two insufflations of boric acid. But this, again, is a very rare exception, and proves nothing as to the relative superiority of boric acid to other agents. It is impossible to explain how an agent which will put a stop to an otorrhœa in two days, and that, too, with a single daily application, will, in a dozen other cases which present to examination almost the same objective features, demand many days to do any good, and frequently fail to cure completely.

Bacteriological researches in cases of suppurative inflammation of the middle ear have been recently made by Zaufal,[1] Moos,[2] Rohrer,[3] and Netter.[4] According to these investigators, four distinct species of pathogenic micro-organisms are concerned in the production of suppurative inflammations of the middle ear, sometimes one and sometimes more than one variety being found in the same case. These organisms are the micrococcus Pasteuri, discovered by Sternberg in his own saliva, and recognized by him as the cause of sputum septicæmia in rabbits—and subsequently by Fraenkel, Weichselbaum, and others as the cause of croupous pneumonia in human beings (diplococcus pneumoniæ); the bacillus pneumoniæ of Friedländer, the staphylococcus pyogenes, and streptococcus pyogenes. In fetid otorrhœa bacilli and cocci are always found; in non-fetid cases only cocci (Zaufal). The streptococcus are found most often associated with serious complications, as, for instance, subcutaneous abscesses, mastoiditis, meningitis, purulent infection. That we possess in bichloride of mercury the most perfect of germicides has been amply proven, and upon theoretical grounds, then, did Kretschmann, a little over a year ago, suggest that a sublimate solution be employed in suppuration of the middle ear. From experience I can testify to the value of the suggestion, and from an antiseptic point of view the question hardly admits of argument.

To sum up: 1. Carbolic acid, to get its full antiseptic value, must be employed in a solution too strong to be used in the ear without doing positive harm. 2. Iodoform will not be tolerated by the majority of patients, and did not give me as good results as boric acid. 3. Inasmuch as the recent experience of aural surgeons has shown that the use of boric acid in the powder form is associated with danger,[5] I comparatively seldom use the agent in this form. In the saturated solution boric acid is a valuable agent. 4. If the ear be thoroughly cleansed with warm water, and the acid sublimate solution be allowed to remain in for ten minutes or more, and the ear then closed with a pledget of cotton which has been moistened with the solution, the clinical observations of the past few months have led me to conclude that this solution has a somewhat larger field of usefulness, and will show a somewhat larger percentage of cures than the other three agents.

## THE TREATMENT OF PULMONARY TUBERCULOSIS.

By E. LICEAGA, M.D.,

PROFESSOR OF THE SCHOOL OF MEDICINE, PRESIDENT OF THE BOARD OF HEALTH, DIRECTOR FOR THE HOSPITAL FOR CHILDREN, AND MEDICAL DIRECTOR FOR THE MUTUAL LIFE INSURANCE COMPANY OF NEW YORK, COMPANY'S AGENCY IN THE CITY OF MEXICO.

BEFORE expressing my views in relation to the treatment of pulmonary tuberculosis by the use of calomel, I will explain how I arrive at the application of mercurials in tubercular affections of the lungs.

From time immemorial tubercular meningitis in children has been treated with calomel as well as with the application of mercurial ointment, and favorable results have been obtained. I, myself, have succeeded in curing a child when already in an advanced stage of this malady, and also many other cases, provided no serious effusion had taken place in the arachnoids, or, at least, when such effusion was not copious.

It will be remembered that Dr. O'Beirne recommended the use of mercurial preparations for combating scrofulous arthritis of the hip and knee, and that this treatment, employed by many physicians, was sufficient to arrest the progress of so terrible a complaint, provided it had not reached the ulcerative period.

Mr. Graves, the intelligent Dublin clinician, well acquainted with Dr. O'Beirne's views upon the subject, was inspired with the idea of treating scrofulous bronchitis and pneumonia by the use of mercurials. Mr. Graves advises their employment whenever the illness commences with a scrofulous inflammation of the lungs. "Only in such cases are mercurials to be tried, and even then they are of no service, except when the pulmonary affection has suddenly commenced under the influence of an efficient and well-known cause—such as cooling off, or an hæmoptysis."—"Lessons on Medical Clinics," by Dr. R. J. Graves, translated into French by Dr. Jaccoud. Paris, 1863. Lesson 45, p. 172.

I cannot attempt to follow the author in his demonstration that mercurials have to be employed in scrofulous bronchitis and pneumonia, in persons predisposed to phthisis, but prior to the development of the general phenomena; in a word, when in his judgment there is as yet no phthisis. Notwithstanding, I cannot abstain from quoting the following: "When, in a scrofulous person, a sudden cold has determined the inflammation of the bronchial mucous membrane, or of the pulmonary tissue, in case the cold is recent and there is no reason to suspect the existence of tubercles, mercury succeeds admirably in arresting the progress of this malady, which, neglected or improperly treated, would most probably end in phthisis." Ibid., page 176.

Should any doubt be entertained relative to the author's views, Mr. Jaccoud, the translator, removes it in a note on the same page of the quoted work, commenting on this phrase of M. Graves:

"In spite of this restriction this method is, in my opinion, a most valuable acquisition for certain complaints which have a tendency to degenerate into phthisis." Mr. Jaccoud's annotation runs thus: "I expressly call attention to this last phrase, in order to prevent attributing to the author any idea of treating phthisis by mercurials, a fact which might happen by resorting to any of those erroneous interpretations which are so common. Mr. Graves reserves this medicament for inflammatory affec-

tions which develop in scrofulous individuals, and have a tendency to degenerate into phthisis."

Resting upon this opinion, and upon the fact, often observed by me, that *tabes mesenterica* can be cured by the use of English blue mass, I resolved to apply mercurial preparations in the case of persons undoubtedly affected with tubercles.

The first individual coming under my observation was a young lady eighteen years of age, who, up to that time, had enjoyed good health, and in whom an intense bronchitis appeared, which was soon accompanied with fever, sweats, marked loss of flesh and appetite, and other disturbances of the digestive apparatus. When convinced that the disease would not yield to the remedies prescribed in these cases, an examination of the patient led me to discover that there was an induration in the apex of the right lung; and then I subjected her to the use of calomel internally administered, by frictions of mercurial ointment, and to applications of light blistering plasters in the subclavian region and adjacent parts. When gingivitis showed itself I discontinued the application of mercurials. Due either to the use of these preparations, or because the inflammation of the gums prevented the patient from eating, her strength was diminished, and in her countenance might be noted the deterioration which her organism had undergone; but her condition in general soon improved, fever and sweats ceased, the appetite returned, the cough rapidly diminished, her strength came back, and the indications of pulmonary induration gradually and totally disappeared. This, which was the first application of mercurials made by me, occurred in the beginning of, 1871. The patient is still alive and enjoys perfect health. I communicated the result to the members of the *Sociedad Familiar de Medicina*, and in subsequent cases treated by me, I took especial care that the same gentlemen, or other distinguished physicians of this city, should verify the existence of pulmonary tuberculous infiltration; and when we agreed in the diagnosis, I proceeded to the application of the method.[1]

The results obtained were, in every case, the more or less rapid cure of the patients, with the exception of two cases—one treated by me and the other by Dr. Brassetti—both of which cases had reached the period of pulmonary ulceration, and in whom wide cavities were encountered.

It would be impossible, in a short communication, to state the numerous observations collected by me from patients in similar conditions to the one I have used as a type, but as I wish to be exact relative to the circumstances in which the employment of mercurials gives a certain result, I will fix the conditions under which I have used them:

*A.*—Whenever there are indications of pulmonary induration of a tuberculous nature. (Until lately, for my diagnosis, I have resorted to the clinical characteristics accepted by all physicians; but since the *bacillus* in tuberculosis has been generally known, I have added to these means the demonstration of the presence of this microbe in the sputa.)

*B.*—The tuberculous infiltration of the lung, either accompanied or not with intense bronchitis, requires the use of mercurials and blisters.

*C.*—Tuberculous bronchitis requires the same treatment.

*D.*—I employ this method in pulmonary tuberculosis, either recent or of long standing, providing it has not reached the period of ulceration.

*E.*—I also use it when there is either intermittent or remittent fever; whatever may be the state of the digestive apparatus; only if there is diarrhœa I advise a milk diet, and afterward the attack intestinal disturbance with suitable remedies.

I know of but two contra-indications: one is when ulceration of the lungs has led to the formation of large cavities, and the other the complete exhaustion of the patient, since in these cases the sick, instead of being benefited, succumb more rapidly than without such treatment, as happened in the two cases to which I have previously referred.

I should state that the treatment by mercurials and blisters modifies in a rapid and favorable manner the local and general condition of the patient, to such an extent that the patients in many cases have their health entirely restored. This happens in persons who have not been ill long, or when the sickness is of lesser intensity; but in other cases the method indicated opens the way to healing; and, in order to complete the cure, it is necessary to have recourse to other means, which vary according to circumstances. I will enumerate those which I more frequently employ.

To begin with hygiene: A residence in the country; if it be possible, the dwelling facing south or east; breathing a pure atmosphere, exercise in the open air; hydrotherapy when the fever has disappeared; nutritious and wholesome food.

I intentionally omit mentioning the advantage of living in climates of elevated countries, since I wish to make this the theme of another paper, which I will have the honor to forward soon.

After using mercurials I constantly employ iodide of sodium, according to this formula:

℞. Aquæ destill.....grams 50
Iodid. sodii..... " 10

Sig.—Used in drops, to commence with ten, increasing by ten each day, and having reached two hundred, to be recommenced; always administered either in pure or in sugared water. The use of this substance is to be continued for many months.

If this treatment by mercurials has failed to satisfy me, I add to the use of the iodide that of English blue mass.

The frequent use of blisters is suitable, but in order not to fatigue the patient, I recommend the weekly application of a light one (that is to say, not producing suppuration) in different parts of the thorax, giving the preference to the affected side. There are persons who need many of them, but commonly ten or twelve are sufficient in incipient cases. As in some patients the repetition of the blisters causes boils around these blisters, they constantly refuse to continue with the treatment; in such cases I substitute blisters by cautery-points at twenty or thirty different places in a limited space of the thorax, using the acute cone of the thermo-cautery of Paquelin; and in this case I repeat more frequently the applications.

As long as there exists any point of the lung indurated, I continue the blister, even should it have to be prolonged for several months.

I always employ blisters for simple bronchitis in tuberculous persons.

Should the pulmonary lesion, although ameliorated, remain stationary, I occasionally return to the use of calomel, administered internally, and mercurial ointment, externally.

Should the patient not recover his previous robust health, but remain delicate, I employ arsenic, in the form of the arseniate of strychnine:

℞. Extracti cinchonæ..... gr. 4
Arseniatis strychnici..... gr. 0.03

in thirty pills. Sig.—To commence with one daily at dinner, increasing one every four days. Having reached five pills a day, recommence, using one.

This treatment I also continue for a long period.

I have, unconsciously, come to treat slow developing phthisis, and in a chronic form; but as it often happens that the mercurial treatment, when it does not at once cure, favorably modifies the malady, it becomes imperative to perfect the cure by resorting to less energetic means.

Many patients, and even physicians, become frightened at the deterioration undergone by the health of the sick, while under mercurial treatment; but fever disappears

[1] In 1881 I delivered a lecture on this subject before the majority of the physicians of the City of Guanajuato, my native town.

soon after, sweats cease, cough diminishes in frequency and intensity, appetite and physical strength return, and the patient begins to recover his weight, and becomes convinced of the benefit received.

I do not wish to enter into the theoretical considerations which induced me to employ mercury in the healing of pulmonary tubercles, but I should state that, now that the *bacillus tuberculosus* has become known, every physician has endeavored to find parasiticides which, operating directly upon the microbe, may prevent its development and propagation; creosote, iodine, iodoform, phosphate of copper, tannin, and menthol have been alternately employed, with this object. Antiseptic inhalations and pulverizations with iodine vapors, iodide of ethyl, benzoate of sodium, camphor, turpentine, resin, iodoform; with a solution of biniodide of mercury, with solutions of picric acid, of boric acid, etc. The inhalations of fluorhydric acid have been more carefully studied, and tried on a greater scale. Those of sulphurous acid, those by the rectum with carbonic acid mixed with sulphuretted hydrogen. Hypodermatic injections of different substances have also been used, and even intra-parenchymatous ones, which results do not appear to have been advantageous.

As to the use of mercurials, I do not find any other references than those of which I am about to speak. In a very recent work ("Practical Treatise on Antisepsia," by Le Gendre, Barette and Lepage, Paris, 1888), Mr. Gosselin reports some experiments undertaken in the endeavor to render sterile the organism, either before or after the tubercular inoculation. In the first case, organic impregnation by bichloride and biniodide of mercury did not prevent the development of the bacillus; it rather appeared to hasten the subject's death, debilitating his organism. The administration of the sublimate subsequent to the inoculation has produced the same results. These experiments were made in animals. Hiller made subcutaneous injections of sublimate, which did not succeed in tuberculous patients.

At a meeting of the Hospitals Medical Society (January 8, 1886), Gougenheim made known the results of thirty-three cases, in which he used antiseptic injections in tubercular cavities of the lungs, with solutions of sublimate in the proportion of one to five hundred, to one thousand, or to two thousand, according to the severity of the lesions. No ill results followed, even the cough diminished; when the injection is gradually administered, the first and second intercostal spaces should be selected. In twenty-one cases a very marked improvement was observed in regard to local aspects, but the patient's general condition did not appear to have proportionately improved.

The sole applications made, previous to the discovery of the bacillus, for the cure of phthisis with mercurials, are those which refer to the employment of bichloride of mercury, the iodide of potassium, and the sesquicarbonate of sodium. I intend to follow these suggestions and communicate any results which I may obtain.

In the *Therapeutische Monatshefte*, Prof. Dochmann wrote under date of September 15th, that he had commenced the use of mercury in phthisis, taking into consideration the microbic nature of the malady, and asserting that no one previous to himself had resorted to this treatment.

The contents of this communication prove that before the year 1871, not only had it been tried, but that the mercurial treatment had also been successfully applied in Mexico.

City of Mexico, January 10, 1889.

---

The One Who Trembled.—Madame de Sévigné in one of her letters sent the following anecdote to a friend: "The Prince once said to his new surgeon: 'Do you not tremble when you bleed me?' And the little surgeon answered: 'Pardon, sir, it is you who tremble!' and he told the truth."

# Clinical Department.

## AN UNUSUAL CASE OF LARYNGEAL INTUBATION.

By A. BROTHERS, M.D.,

Attending Physician for Diseases of Children, Out-door Department, Bellevue Hospital, New York City.

Intubation of the larynx has, according to Dillon Brown, been performed in two thousand three hundred and sixty-eight cases, and is fast replacing tracheotomy, in this country, as the operation to relieve laryngeal stenosis. As the method, however, is still comparatively new, every case with unusual features deserves being placed on record for the guidance of others.

On April 6, 1889, I was requested to take charge of the seventeen months old baby of Mr. S——. Two weeks previously—on March 23d—Dr. F. Huber, assisted by Dr. A. Schlesinger, intubated the child for laryngeal obstruction due to ascending croup. This was followed by immediate relief. A week later (March 30th) Dr. Huber removed the tube but, owing to recurring dyspnœa, it was immediately re-inserted. On April 5th the tube was coughed out, and during the ensuing twenty-four hours the difficulty in breathing grew worse and worse. When I assumed charge of the case, on April 6th, the child was in a desperate condition, with all the evidences of advanced croup. I succeeded in introducing a two-year tube, with instantaneous relief. Next day the breathing and temperature were normal, and the child was nursing with perfect ease. A week elapsed and the child being apparently entirely well, I removed the tube (April 13th), but within an hour I was obliged to reinsert the same tube. Eight days later (April 21st) I removed this tube and, at the same sitting, replaced it by a one-year tube. This double procedure, done with the assistance of Dr. A. T. Joyce, occupied less than a minute. My object was to have the child cough out this smaller tube, as my experience has taught me to prefer this termination to extraction. Three days later (April 24th), as the child had not coughed out the tube, I felt justified in removing it. Drs. Muldberg and Finklestein were present at the time. After some difficulty—for the tube seemed imbedded in œdematous tissues—the tube was extracted, and this was followed by the coughing out of bloody mucus in larger quantity than I had ever before witnessed. The breathing at once became very labored, and in three minutes the child was suffocating and cyanotic. On the spur of the moment I attempted to introduce a tube without mouth-gag or thread, but the tube slipped down the œsophagus and was swallowed—an accident which had never happened to me before. The gag was at once placed between the teeth, and as the child seemed to breathe its last, I succeeded in getting the small tube into the larynx. The tube which entered the stomach was not noticed by the parents during the excitement of the terrible moment, and I did not wish to alarm them by calling their attention to it. At all events I never heard of it afterward, and presume it was passed unnoticed with a movement from the bowels and thrown away. On the night of April 9th the last tube was coughed out, but as the breathing was somewhat difficult, and as I feared trouble during the night, I preferred to re-intubate. This tube was worn continuously for three weeks—from April 29th to May 20th—when it was expelled during a severe paroxysm of coughing. Since then the child has been in perfect health.

A few reflections on this remarkable case may not be out of place. One of the most interesting questions was in regard to diagnosis. Dr. Huber informed me that, at the time of the first operation, the child was suffering from ascending diphtheritic croup; and I accepted his diagnosis without question. When I first saw the child, two weeks later, the throat was perfectly clear, temperature normal, and beyond some bronchial catarrh, the only condition

present was that of laryngeal stenosis, for which I intubated. After the child passed through the alarming experience of April 24th, when it almost died in my presence, I wrote to Dr. O'Dwyer asking his opinion in regard to the diagnosis and subsequent treatment of the case. He promptly responded, and suggested paralysis of the abductors, or persistent inflammatory œdema as the causes of the long continuance of the stenosis. As the child subsequently coughed the tube out without immediate suffocation ensuing I excluded paralysis, and attributed the stenosis to simple œdema of the larynx. In this view I was supported by Dr. A. Jacobi, who saw the child while it was wearing the tube. Dr. O'Dwyer suggested leaving the tube *in situ*, if necessary, for three or four weeks. This suggestion I carried out, leaving the child alone for three weeks, when it coughed out the tube.

While carrying the tube, it was wonderful to see with what perfect ease the child nursed at the mother's breast. It was only after drinking from the spoon or cup that liquids would enter the larynx, and excite coughing. For several days, while wearing the last tube, a general urticarial eruption made its appearance, but passed away without special treatment.

In looking over the records of published cases, I find that the longest period during which a child carried a laryngeal tube was nineteen days. This was in a child of twenty-six months, intubated by Dr. J. A. Anderson (THE MEDICAL RECORD, July 23, 1887, p. 87). As in my case the tube was worn with interruptions for nearly fifty-eight days, and continuously at the end for twenty-one days, it is the longest case on record in this respect.

Finally, it is interesting to note that the laryngeal œdema undoubtedly present in this case was successfully dissipated by the gentle and continuous pressure exerted by the O'Dwyer tube.

93 MADISON STREET.

## POISONING BY TINCTURE OF IODINE.

DR. A. N. COLLINS, of Detroit, Mich., reports the following case: "I saw the patient, a young woman about twenty years of age, fifteen or twenty minutes after the drug had been swallowed. I found the patient suffering with symptoms of acute gastric irritation and burning of the throat. No other symptoms were marked except those arising from fright at the discovery that the drug was labelled 'Poison.' The patient stated that she had taken at one dose ℥ ss. tincture of iodine, which she purchased that day, and showed me a half-ounce bottle containing a small quantity of tincture of iodine. She had taken the drug by mistake, intending to take medicine from another bottle standing near it. Before taking a little water had been added in a glass, and the whole mixture taken 'at a gulp.' Immediately I gave her a draught of water made thick with starch, followed by a teaspoonful of mustard flour given in water. This was followed by a copious draught of warm water. Vomiting was immediately produced, the vomited matter having the blue color of iodide of starch. I repeated the dose several times until no color-change was produced on the starch, and then gave, hypodermatically, morphine sulphate, gr. ¼; atropine, gr. $\frac{1}{150}$. I left the patient free from pain. Saw her next day and found no trouble beyond an indisposition to take food, and soreness over the epigastrium. The next day the patient was about her work seemingly as well as before her mistaken medication. Judging from this case, I draw the conclusion that tr. iodine, when antidoted, is not so harmful in effect as has been reported. The patient had taken no food for six hours before taking the drug."

AN ŒDEMIC TIDE.—The Boers of South Africa believe that the moon exercises an influence over dropsy, and that the water is always worse at full-moon and wanes as the moon wanes.

# Progress of Medical Science.

A NEW METHOD OF AUSCULTATION.—Dr. Carlo Giorgeri has recently described (*Gaz. degli. Ospitali—British Medical Journal*) an addition to the methods of physical examination at present in use, of which a short preliminary account was given by Professor Aurelio Bianchi, at the Medical Congress held at Rome in October, 1888. That gentleman, on passing an œsophageal tube into a patient's stomach, and applying his ear to the upper end, heard various sounds as the instrument travelled down the gullet, and when its lower end was in the stomach. By fixing a bifurcated, gum-elastic tube, provided with ear-pieces like those of a binaural stethoscope, to the upper end of the œsophageal sound, he contrived an instrument with which he was able to practise what he calls "endo-auscultation," both of the œsophagus and the stomach. Dr. Giorgeri divides the sounds heard in this mode of examination into (1) œsophageal, (2) gastric, (3) respiratory, and (4) cardiac. The œsophageal sounds are produced by the rubbing of the instrument against the walls of the gullet; they are loudest at the two narrowest points of the œsophagus, namely, at its upper aperture opposite the posterior surface of the cricoid cartilage, and at the cardiac orifice. There may also be one or more strictured portions where the sounds are heard with special intensity. Peculiar sounds are caused by abnormal conditions of the walls of the œsophagus, or by foreign bodies adherent to them; and gurgling may be heard if the instrument enters a diverticulum containing fluid or solid food. The sounds heard in the stomach are chiefly of a gurgling nature, or they may be caused by friction against foreign bodies, or against the walls of the viscus altered by organic disease, or by sudden sharp contractions of the organ. The respiratory sounds begin to be heard as soon as the instrument enters the upper aperture of the œsophagus, and increase in intensity as it travels downward, being most distinct a little above the cardiac orifice. If the walls of the stomach or œsophagus are the seat of structural changes, the transmission of the breath-sounds is interfered with to a greater or less extent. The heart-sounds are heard from the middle of the œsophagus downward, and in the stomach. The two sounds are distinct, but more blowing in character than when heard in the ordinary way. Professor Bianchi made some experiments on the effect of the introduction of fluid into the stomach on the sounds heard by endo-auscultation. For this purpose he modified the instrument, by fixing a bifurcated tube to the upper end of the œsophageal sound, one arm of which was of considerable length, and was fitted with a glass funnel at its free extremity, while the other arm was again bifurcated, the two ends being provided with ear-pieces as before. If, after introducing the instrument, fluid was poured through it into the stomach, the cardiac and respiratory sounds at once ceased, and could not again be heard, even on drawing up the œsophageal tube so that its lower end was above the level of the fluid in the stomach, while in the œsophagus itself the heart- and breath-sounds were very indistinct. If the stomach was then emptied, and the instrument again introduced, some time elapsed before any sounds were audible. Professor Bianchi offers as an explanation of this curious effect that, as the vibration of membranes is more perfect the drier and more tense they are, the introduction of fluid impairs the vibratory power of the stomach-walls. He believes that endo-auscultation may prove of great service in the study of diseases of the stomach and œsophagus, and possibly of the circulatory system in the thorax.

NEW REMEDIES FOR SKIN DISEASES.—Schwimmer has lately, in the *Wiener medizinische Wochenschrift*, published the results he has obtained in certain skin diseases by the use of salol, oxynaphtholic acid, salicylate of mercury, and anthrarobin. Salol mixed with starch in the proportion of two to one he finds a very effective remedy in all forms

of venereal sores and in the buboes resulting from them. Iodoform seems to have a more rapid action, but salol has the superiority of possessing no smell. The drug also appears useful in conditions of the mucous membrane of the bladder, when given internally in doses of forty-five to ninety grains distributed through the day. Oxynaphtholic acid did not give good results in venereal cases, acting as an irritant. In scabies, however, it did not irritate, and was an effective remedy. It may be mixed with chalk and soft soap, each ten per cent., with lard. It acted well also in the secondary eczema of scabies, and allayed itching in prurigo. Salicylate of mercury possesses no superiority over the ordinary remedies used in gonorrhœa and venereal sores. Given internally in doses of one and a half to two grains, it was an effective antisyphilitic drug, although apt to cause irritation of the intestine and stomatitis. Anthrarobin was found to have no beneficial effect in psoriasis, but in herpes tonsurans, eczema marginatum, and pityriasis versicolor it acted well, being mixed with collodion in the strength of one in ten.—*Brit. Med. Journal.*

The Influence of Morphine on the Uterine Apparatus.—Dr. Lutaud communicated to the Paris Société de Médicine, three years since, a paper drawing attention to a hitherto unrecognized symptom of the morphine habit. He had found, in a limited number of observations, that morphine exercised a peculiar influence on the ovaries, diminishing and even abolishing menstruation. He now publishes a further and extended series of observations of the same kind, which not only confirm his previous assertions, but afford several therapeutical indications of value. He has remarked the total suppression of the menses in eighteen cases as soon as the amount of morphine attained a certain dose (*The London Medical Recorder*). All the patients had taken to morphine on the advice of their medical attendant for the relief of uterine disorders, which, however, had in every case ceased to exist when they came under observation. The suppression of the flow was therefore due to the influence of the drug and not to the primary ailment. He gives the history of eight characteristic cases of women, under forty years of age, in whom suppression of the menses had taken place with a minimum daily dose of four and a half grains of morphine. He concludes (1) that morphine has an elective action on the uterus, suppressing menstruation and extinguishing the reproductive function; and (2) that this elective influence is characterized by the extinction of all sexual desire. He suggests, therefore, that morphine would prove of service in the treatment of women suffering from affections which are aggravated by the menstrual flow, such, for instance, as fibroid. He has put it to the test in cases of fibroid and cancer of the uterus, and the results appear to him to have been satisfactory.

Malarial Paroxysms in the Fœtus of a Healthy Woman.—In the *Edinburgh Medical Journal*, June, 1889, Dr. Felkin relates two cases in which he observed malarial paroxysms in the fœtuses of healthy women. He suggests the rather striking explanation that the malarial poison was introduced in the semen of the diseased father at the time of conception of the fœtus. In one of the two cases the mother, an English lady, more than eight months pregnant with her first child, consulted him for "pain and a curious sensation in her abdomen." She said she had had several such attacks during her pregnancy, but they had never been accompanied by pain. The attack was sudden. On palpating her abdomen Dr. Felkin distinctly felt the fœtus shaking. The next night, and again the next, the same thing occurred at the same hour. On the fourth night he found her again in the same condition. Labor had set in, the head presenting at the dilated mouth of the womb. As the pains became feeble, and progress ceased, he put on the forceps, and easily delivered the head. The body was extracted with difficulty, on account of the great distention of the abdomen by an enlarged spleen. The child lived, and after seven attacks of ague —with cold, hot, and sweating stages—recovered health, the spleen returning to about its normal size. The mother of this child had never suffered from malaria in any form whatever, the father had experienced very severe intermittent and remittent ague attacks while living in a distant part of the country, and was suffering from them at the time of the conception of the child. In the second case, a Scotchwoman, seven and one-half months pregnant, was ill with pleurisy and bronchitis, and the effects of a beating which her husband had given her. At one of Dr. Felkin's visits the nurse told him that she had suffered on the previous night from a "pain and fluttering in her abdomen like a bad quickening." Being called the evening of the same day at the same hour, he found her in a condition very like that observed in the former case. Two evenings later, after another similar paroxysm, labor set in, and the child was born before he could reach the house. Its abdomen was slightly enlarged. On the night after its birth it had a cold spell, with shivering, lasting half an hour, succeeded by a hot stage of two hours, and a stage of free perspiration. The temperature during the attack ran up to 102.6° F. On the second night after its birth it died in the cold stage of a similar paroxysm. On post-mortem examination the kidneys showed marked cloudy swelling in the epithelium of the convoluted tubules, the nuclei of the cells continuing to stain while the surrounding protopasm was highly granular. The nuclei of the glomerular cells stained distinctly. In the liver many leucocytes were seen to contain very numerous fine granules of a dark brown color. The venous sinuses of the spleen were dilated. Dark pigment granules were observed in many of the leucocytes contained in the sinuses, as well as in the endothelial cells lining them, and in the cells of the surrounding connective tissue. The mother of the child had never suffered from ague. She had three healthy children by her husband. He then went abroad and contracted severe malarial fever. Ten months after his return a feeble child was born, which soon died. About a year later a second child was born, which was sickly and had an enlarged spleen. In these two pregnancies the mother had the same strange feelings like quickening. Dr. Felkin thinks that these cases show that malaria is a specific disease, due to a micro-organism, which may be transmitted by the father to his offspring, just as syphilis may be transmitted.

Psorospermial Cysts of Ureters.—At a recent meeting of the London Pathological Society (*The British Medical Journal*) Mr. Eve showed a specimen which had been sent by Dr. J. Arnallt Jones, of Aberavon, to Mr. Hurry Fenwick, who had handed it to Mr. Eve for examination. The upper parts of both ureters were studded with small miliary cysts full of milky contents. Transverse microscopical sections of the ureters showed cysts of various sizes filled with colloid material, in which were many ovoid bodies which corresponded in appearance and size to psoro-navicellæ. The patient was a woman, aged fifty-one, who had a sudden attack of hæmaturia, with frequent and painful micturition. Death had taken place from exhaustion and anæmia seventeen days after the onset of symptoms. The kidneys and bladder were healthy. Psorospermial cysts had been found beneath the capsule of the human kidney and in the liver. The disease was not uncommon in some domestic animals, and it was very common in the livers of rabbits.

---

Medical Scepticism.—At the time when Russian society was at the height of scepticism, the eminent Professor, N. G. Pirogoff, said in one of his celebrated public speeches that the life of every physician may be divided into three periods. The first, when he religiously believes in what he has been taught at the university; the second, when he only believes in what his own experience taught him; and the third, when he believes neither in one nor in the other.

# THE MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, July 27, 1889.

## THE HISTORY AND COST OF THE DIDACTIC LECTURE.

IT is evident to anyone who has watched the progress of medical education in recent years that the didactic lecture has suffered a great decline in relative importance, as compared with other methods of imparting professional knowledge. Indeed, it is not hazardous to prophesy for it a still further decline in the near future. Nevertheless, it is of interest to study its origin, as its history illustrates an important phase of evolution in the educational world.

We understand, by a didactic lecture, a teaching of abstract truth relative to disease, while the clinical lecture supplies its concrete correlative. The former is a heritage from our fathers. It sprang into being even in the early ages of the world. In our own country it antedates schools and colleges. It had its origin at a time when the minister and the doctor were the only learned men in the community. Books were scarce. Access to the fountains of printed knowledge, particularly in the professions, was granted to but few. Hence came the imparting of information by the physician to his office assistants during the consulting hour, and during the lonely ride. The number of those giving and those receiving instruction gradually increased, so that, to avoid duplicating instruction, the teacher met all his pupils at one place. That was the beginning of a college, and from that origin has been gradually wrought out the medical school of to-day.

That was the best system for its day. In fact, it was the only possible one under the existing conditions. Information was locked up in the brains of a very few. It was not accessible to the many. Now all is changed. The multiplication of the printed page has brought the best and ripest scholarship within the reach of all. Yet the average didactic lecture has run on in the old groove.

In view of this modern progress, the lecturer who has maintained the old reputation of his craft has had to possess an endowment of personal magnetism and enthusiasm to hold his audience. A notable illustration of this was the late Dr. Dalton. His text-book contained practically all that was said in his lectures; but who can forget that breadth of explanation, that contagious love of the subject which pervaded his class-room utterances? It is not given to all lecturers to possess this quality. Now and then a man has the art of expounding his subject well, of making students think for themselves. But the average didactic lecture is dry and, unless the lecturer is an original worker, unmistakably dull. It is retailed out so many times in the course of a session for so much. The information is generally crammed up from a large collection of text-books, flavored with a little experience, and doled out by the hour: price, twenty dollars per session.

No wonder, then, that many didactic lectures are poorly attended. The student knows that he can find all the information in text-books, and sees no reason why he should listen to another's reading of the same. Particularly is this true of a subject like anatomy. It is not a fault of any one man or any one institution. It is a universal one.

The average medical session lasts about twenty-four weeks. The total number of lectures will average, in any one branch, about eighty. The prevailing price for any one study is twenty dollars. The didactic lecture, therefore, has a market-value of twenty-five cents. Inasmuch as a student is compelled to attend two courses of lectures which, in the primary branches, are practically duplicated, he is obliged to buy the article twice over. In a college of six hundred students the gross revenue will, on the above basis, amount in each of the seven departments to about eight thousand dollars.

The successful medical curriculum should be arranged on such a broad basis that to pass in a given subject should not necessitate attendance on the lectures of any one man. It should be broad enough to include knowledge in that branch generally. The didactic lecture will, we believe, gradually give way in the future to a judicious and well-ordered system of recitations. A lesson will be assigned in a text-book and recited, and the medical instructor will assume the functions of the regular teacher of science. This is already the method in the medical departments of Harvard, Yale, the University of Virginia, and some other institutions we might name. Collateral reading is encouraged, and a much broader foundation is laid than by the system so widely prevalent.

## CHROMIC ACID IN SWEATING OF THE FEET.

IF all remedial measures could be subjected to such extensive and compulsory tests as has the chromic-acid treatment of sweating feet, we should soon arrive at many therapeutical certainties.

On July 9, 1888, orders were sent out to all the military surgeons of the Prussian army to use chromic acid in all cases of sweating feet. The directions were that if there be any broken surface the solution must not exceed five per cent. till it heals, after which the solution may be increased to ten. If the sweating be of a moderate character the application must not be made oftener than every six or eight weeks, but if very intense it has to be applied every fortnight for the first month. In the height of summer the whole body may be similarly treated, but two applications are considered sufficient to relieve the most obstinate cases, and it is said to leave no bad effects. This assertion must, however, be received with a certain amount of caution, says the *Medical Press*, as a death following its use caused the order from headquarters to be modified, though it has been assumed that the death was caused by the use of an impure solution. The first order was sent out July 9, 1888, and this modification on No-

vember 30th of the same year. Since then its use was limited to the five per cent. solution in all cases till they proved obstinate.

A report on the results of the use of this remedy was sent in in January, 1889. There were upward of 18,000 soldiers treated by chromic acid during the six months over which the report extends, and the result of the experiment is decidedly favorable. Of these 18,000 patients forty-two per cent. were cured, fifty per cent. improved, and eight per cent. unaffected.

The report subdivides the cases into three degrees of severity: 1. A severe form in which the skin of the foot is constantly wet, red, and swollen, particularly between the toes, the foot tumid and macerated, in which cases the sweat rapidly decomposes and produces an intolerable stench. 2. A middle class is given, of cases in which the sweating is confined to the sole of the foot, which also produces dampness and fetor. The third class comprises cases due to much walking on very hot days. The solution must not be applied by means of brushes made with metal holders, as the chromic acid is apt to decompose the latter, and on this account wood is to be preferred. Again, if bathing the feet be allowed, it must be done in an earthenware utensil for the same reason; but the brush is by far the best means of applying the solution.

---

### DILATATION OF THE MALE URETHRA FOR THE REMOVAL OF VESICAL CALCULI.

Dr. Laplace (*New Orleans Medical and Surgical Journal*, June, 1889) reports a case of vesical calculus in a feeble patient, aged fifty-six, who came under his care in October, 1888. He complained of great difficulty in passing water, the stream being full at first, but suddenly stopping before the bladder had become quite empty. Micturition was accompanied by a burning pain at the neck of the bladder. His urine contained about three per cent. of albumen, some pus, and a large quantity of mucus, the bladder being evidently inflamed. His temperature was constantly above 99° F. Upon exploration, calculi about the size of a chestnut were discovered in the bladder. Influenced by the good results claimed last year by Küster, from Küster's modification of Delbeau's operation, which is a para-prostatic section of the urethra with subsequent dilatation of the prostatic urethra and neck of the bladder, Dr. Laplace determined to attempt removal of the calculi by this method. Chloroforming the patient, and placing him in the lithotomy position, he introduced the index of the left hand into the rectum, so as to feel the anterior edge of the pronati, and cut, in the median line, through the perineum, directly upon the guide in the urethra, and, having reached the guide, continued his incision to within a quarter of an inch of the prostate. The whole incision was an inch and a half in length. The guide was then withdrawn from the urethra, and the operation of dilating the prostatic urethra and the neck of the bladder was begun. The whole urethra had been somewhat dilated already by the passage of sounds during several preceding days. Through the perineal incision Simon's dilators were introduced, beginning with No. 1 and ending with No. 8, each being left in position five minutes. When No. 8 was removed, two fingers were easily passed into the bladder, and, after the two calculi had been accurately located, an ordinary forceps was introduced, and they were easily removed. The bladder was thoroughly explored by the fingers, to make sure that no fragments were left behind, and the viscus was then washed out with carbolized water. Two sutures were applied at the extremities of the perineal wound, and the case was treated subsequently as one of simple external urethrotomy. For ten days the urine was passed through the wound in the perineum, but gradually began to flow through the urethra, and on the twenty-sixth day after the operation the perineal wound healed. For a few days after the operation the bladder was washed out through the incision. The patient recovered completely. Sounds were passed daily, after the wound had healed, for the purpose of securing a permanent open condition of the urethra.

Dr. Laplace thinks that this operation, though as yet but little known, will lead to a great improvement in the surgery of the urinary bladder. He concludes with a summary of the points of greatest interest.

1. The operation is very simple; little more, really, than an easy external urethrótomy.

2. The prostatic urethra may be dilated very greatly, with ease and with impunity. This might be naturally inferred from the muscular structure of the prostate, and from the great dilatation of which the uterus, which in the female corresponds to the prostate, is capable.

3. Having now a safe means of access to the male bladder, free from danger to that viscus, there is no reason why we should not, to a very great extent, abandon the old methods of extracting calculi from the male bladder, and employ instead this new method, by which we may with facility extract calculi of any size, with or without crushing, avoiding the serious risks of the older operations. It is suggested that this is a very safe and easy method for the removal of foreign bodies from the urethra and the bladder.

---

### LATE PREGNANCIES.

A correspondent writes us regarding the age at which women cease to bear children; or, more specifically, he raises the medico-legal question whether there is an age at which a virgin may be pronounced incapable of bearing a living child, if afterward married or deflowered.

There have been several English decisions to the effect that women of fifty-three or fifty-five years have passed the childbearing age, and if any definite limit can be laid down it is probably about this time. Cases of pregnancy up to the fiftieth year are not very uncommon, according to Tidy. In the famous Douglass peerage case it was established that Lady Jane Douglass, when fifty years of age, gave birth to twins, both of whom lived. Briand cites two cases of delivery, one at sixty-three and one at seventy years of age. There are several cases on record, some well authenticated, of pregnancies occurring between the ages of fifty and sixty. Orfila, for example, cites the case of a woman who had seven children, one at forty-seven, the seventh at sixty. She menstruated until she was ninety-nine years of age! In many of the cases of late pregnancies the whole childbearing period seems to be delayed, so that they cannot be brought up as illustrations of the possibilities of the average woman.

Reports of cases of pregnancy occurring after the age of sixty are but few, and not well substantiated. So that the

extreme limit of possible childbearing may be put at sixty; the limit rarely exceeded, at fifty-five; and the limit ordinarily not exceeded, at forty-five.

As the limit of early pregnancy is eight years, it follows that childbearing is possible in woman between the ages of eight and sixty years.

---

### THE SURGICAL TREATMENT OF TUBERCULAR PERITONITIS.

SURGEONS have somewhat blindly stumbled upon the fact that tubercular peritonitis is a disease which is sometimes amenable to treatment. In 1862 Sir Spencer Wells opened the abdomen to remove a tumor, and found tubercular peritonitis. He drained it and the patient got well. In 1879 Mr. Tait diagnosticated a case of tubercular peritonitis, and treated it by opening the abdominal cavity and washing out the peritoneum. Schwartze has collected seventeen cases in which surgeons have opened the abdominal cavity, discovered tubercular peritonitis, and treated it by washing or drainage, or both. In 1887, Kümmell collected forty cases in which the diagnosis of tubercular peritonitis was first made, and operation for its relief performed. Mr. Robert O'Callaghan, in the June number of the *Dublin Journal of Medical Science*, reports four cases, three of which were successful, and he calls attention to the importance and value of surgical treatment.

Chronic tubercular peritonitis is not a frequent disease, and little is said about it in most standard works. Laparotomists have apparently shown, however, that it is not so rare a trouble as has been supposed, and most important of all, they have shown its curability in a minority of cases. Mr. Tait, we believe, claims that tubercular peritonitis is not really tubercular, but on what grounds we are unable to say.

It has to be borne in mind that some cases of tubercular peritonitis recover spontaneously. Deschamps believes that those cases in which the infection occurs through the genital or intestinal canal have a more favorable prognosis. On the other hand, Treves has shown that laparotomy for tubercular peritonitis has always been unsuccessful in young children.

The diagnosis of the disease is not always easy. Primary tubercular peritonitis runs a somewhat obscure course. The principal diagnostic symptoms, according to Cimbali, are low temperature, comparative absence of pain and tenderness, and copious ascites.

---

METHACETIN—A NEW ANTIPYRETIC.—Dr. Franz Mahnert, assistant to Professor von Jaksch, describes, in the *Pharmaceutische Post* for April 7, 1889, the most recent addition to our rapidly growing list of synthetic medicinal compounds. This time it is an antipyretic, and in composition might be described under the name of para-acetanisidin, its formula being

$$C_6H_4 \begin{cases} OCH_3 \\ NH.C_2H_3O. \end{cases}$$

In doses of from two to three grains, given to children, it exerts a marked antithermic action, the reduction of the temperature being gradually produced, remaining for several hours at the lowest point, and then gradually increasing. Frequently marked perspiration is produced by its use within an hour after its administration.

## News of the Week.

THE LIBRARY OF THE LATE DR. JEWELL, OF CHICAGO, numbering about 3,000 volumes, has been secured as the nucleus of a medical library. Dr. Jewell's portrait, it may be remembered, was purchased by the New York Neurological Society and presented to the Academy of Medicine.

THE GOVERNMENT OF CHILI has created a "Superior Council of Public Hygiene," consisting of seven members, whose duty it shall be to advise the Government in everything that relates to the public health throughout the Republic. The Council has a laboratory for chemical analysis under its control.

THE recent legislature of Texas voted $50,000 for the establishment, at Galveston, of a medical branch of the State University.

M. BROWN-SÉQUARD announces that the injection of ovarian tissue-juice into debilitated women has been tried and without bad effects. He also says that the stimulating effect of the hypodermic injections made upon himself continues, he having now gone sixteen days without any repetition of the injection.

ZOSTER-EPIDEMICS.—Professor M. Kaposi, in a recent clinical lecture, says that nearly every spring and fall there occur epidemics of herpes zoster in Vienna; the favorite months are March and April, October and November.

DISPENSARIES IN CHINA.—The *China Medical Missionary Journal* says: "In Southern China, numerous preaching halls are opened to counteract the influence of Gospel halls, and dispensaries are established to render the dependence of the people on foreign doctors unnecessary. Girls' schools, too, are opened in Canton, near to those of our missionary ladies, with a view of taking away the scholars and saving them from contamination by false doctrines." An account is given of a hospital for incurables, established in Canton, to which there were, during one year, nine hundred and thirty-seven admissions with six hundred and seven deaths.

A GOVERNMENT HELPS A MEDICAL JOURNAL.—The Chilian Government having agreed to increase the grant to the Medical Society for the expenses of their journal, the *Revista Médica*, the editor promises that it shall be very much enlarged and improved. It has been in existence for some seventeen years, but has not obtained a sufficient circulation to enable it to attain financial success.

AN ATTEMPT AT BLACK-MAIL of the most serious and despicable character was recently made against Mr. Malcolm Morris, of London, by a black-mailer named Grandy and a prostitute co-conspirator. They charged Mr. Morris with having, after immoral relations with the female prisoner, broken a promise of marriage made to her, but they were met, unexpectedly, by Mr. Morris handing them over to the police. It was then ascertained that this was not by any means the first speculation of this sort by the pair, and, notwithstanding the plea of their lawyer, that they had simply mistaken Mr. Morris for some other person, they were "sent up" for five years and eighteen months respectively.

EXECUTION BY ELECTRICITY.—Dr. B. Sachs, of this city, writes: "Your short editorial in the RECORD of July 20, 1889, on 'Death by Electricity' contains, among other statements in which I concur, the remark that 'the question is really and solely one of æsthetics.' As one of the expert witnesses in the Kemmler case, I beg permission to give a few figures which are intended to show that the æsthetic difficulties are not greater than the mechanical ones. Few medical men, I am sure, realize the data involved in this problem of execution by electricity. It has been proposed to use a dynamo yielding 1,500 volts. According to Jolly, Gärtner, and others, human resistance is often equal to 500,000 ohms (in round numbers). Now what would happen in case a criminal offering such resistance were subjected to the current of 1,500 volts? Ohm's law reads: Current strength equal electro-motive force, divided by resistance; or, $C = \frac{E}{R}$. In the above case $C = \frac{1500}{500000}$, or $\frac{15}{5000}$, or $\frac{3}{1000}$ amp. Instead of being killed, the criminal would receive at the start a current of 3 m.a. Inasmuch as the resistance diminishes quickly, leaving aside the fact that death should be instantaneous, let us suppose that after thirty seconds the resistance had been reduced to 50,000 ohms, the equation would then read: $C = \frac{1500}{50000} = \frac{3}{100}$ amp., or about 30 m.a.; still a very small current, and far below the 150 or 200 m.a. which many gynecologists use. It is not sufficient to know that a current *may* kill; it *must kill*. A current of fully two ampères would be certain to kill; to send such a current through the body would require a dynamo at least one hundred times stronger than any which has been constructed up to date. You will therefore grant that, in view of such facts, killing *cito et jucunde* by electricity is not as easy a matter as most people suppose; and there is no escape from the conclusion that the gentlemen who proposed using electricity, and those who ordered the plant for the Auburn prison, were not acquainted with the known facts regarding human resistance.

[The question is either misapprehended or not quite properly stated by our correspondent. It is the question of what is the resistance of the human body when proper contact with large, well-moistened electrodes is made. Under these conditions the electrical resistance is neither very great nor very variable. The electrical experts who have referred to the enormous resistances of the human body refer to it as taken under peculiar conditions, and their evidence is consequently not at all to the point. With proper contact the human electrical resistance is not likely to exceed 2,500 ohms, and this is instantly and very much reduced. A current represented by the formula $CS = \frac{1500}{50000}>$, passed through the brain, instantly kills, as experiments on animals show. In consideration of the fact recently shown by Mr. Edison, after testing 250 persons, that the resistance of the human body with proper contact ranges from 660 to 1,500 ohms, and averages only 1,000 ohms, the "expertness" of the testimony which intimates that the resistance is 500,000 ohms may be seriously doubted.—ED.]

DR. PHILIP F. BRAKELEY died at his home in Belvidere, on July 3d, of heart disease. He was for many years Secretary of the Warren County Medical Society, and was a prominent member of the State Society. He was seventy-four years of age at the time of his death.

THE FLOATING HOSPITAL OF ST. JOHN'S GUILD has been making regular trips since July 9th.

THE SEA-SIDE HOSPITAL FOR CHILDREN at New Dorp, S. I., was opened for the reception of patients on July 9th.

THE *Weekly Medical Review* comes to us in an enlarged and improved condition.

AN AMBULANCE SYSTEM FOR LONDON.—A scheme has been brought before the Sanitary Committee of the London County Council for the establishment of an organized ambulance system throughout the metropolis.

DR. THEODORE DIMON, of Auburn, N. Y., died July 23d, aged seventy-two years. He was an old army surgeon, prison physician, and ex-Superintendent of the State Insane Asylum at Auburn.

AT a special meeting of the staff of the Orange Memorial Hospital, held Tuesday, July 9, 1889—all the members being present—the following action was taken upon the death of Dr. Stephen Wickes:

*Whereas*, In His infinite wisdom, our Heavenly Father has taken to himself our beloved colleague, Dr. Stephen Wickes;

*Resolved*, That this staff has lost a most faithful co-laborer. He was zealous and devoted to all the duties pertaining to his office as a medical attendant of this institution. He was an earnest Christian gentleman whose character and disposition were moulded by Christian grace. He was modest, retiring, kind, considerate, charitable, and always ready to give of his time and strength to those in need. He was beloved by those to whom he ministered, and by those with whom he was associated in relieving the sufferings of the sick. Words do not truly express the veneration, respect, and esteem which were accorded to our deceased friend and professional brother by all who knew him within medical circles and by the general community. His literary labors have resulted in the production of much valuable matter, especially of an historical nature, that will serve as a memorial of a useful life. To his family we offer our heartfelt sympathy in their great sorrow, but they still will share with us a joy and comfort that Dr. Wickes was ripe in years, rich in honors, and sure of a reward for a helpful and blameless life.

T. R. CHAMBERS,
THOS. W. HARVEY,
GEO. BAYLES,
*Committee.*

THE AMERICAN RHINOLOGICAL ASSOCIATION will hold its seventh annual meeting at Chicago, Ill., August 28, 29, and 30, 1889. The Committee on the Examination of the Inmates of Insane Asylums will make their report, "On the Relations of Rhinal Inflammations to Mind Affections," at this meeting.

TRAINED NURSES.—The Memphis School for Trained Nurses recently graduated its first class. This is the pioneer training school of Tennessee.

THE STATE OF MINNESOTA, like the State of New York, organized and built an inebriate asylum ten years ago; then they changed it to an insane asylum. A law was passed confining inebriates to insane asylums, and now one of the released inebriate patients makes a protest against this practice.

EUCALYPTOL IN HEADACHE.—Dr. M. J. Lewis (*Medical News*) states that eucalyptol, in doses of five grains, six times daily, is useful in headaches, particularly those of a congestive character.

SIR GEORGE PORTER, of Dublin, who was knighted two years ago, received the higher and hereditary distinction of a baronetcy on the Queen's birthday. It was thought that Dr. Banks, of Dublin, late President of the British Medical Association would be honored in the same way. But he declined a knighthood two years ago, and that is probably the reason why a baronetcy was not offered him.

THE CARTWRIGHT PRIZE ESSAY.—At the recent Commencement of the College of Physicians and Surgeons of New York, it was announced that the Cartwright Prize had been awarded to an essay written conjointly by Dr. Hobart A. Hare and Dr. Edward Martin, of Philadelphia. But the successful competitors voluntarily surrendered the prize because their essay had just been awarded a prize elsewhere. It appears that the essay had been put into competition for both prizes, with the expectation that the decision of one prize would be made early enough to permit them to withdraw from the second competition in case they were successful in the first. But owing to delay in the decision of the prize which should have been announced first, and to absence of the authors from home when the announcement was finally made, there was no opportunity for the intended withdrawal before the award of the Cartwright prize was published. The award of the Cartwright prize has consequently been reconsidered, and the prize has been granted to Dr. Ira Van Gieson, Assistant Instructor in Normal Histology in the College of Physicians and Surgeons of New York, for his essay entitled "Studies in Neural Pathology, embracing (1) A Report of a Case of Syringomyelia; and (2) A Contribution to the Pathology of the Laryngeal and other Crises in Tabes Dorsalis." Signed, Charles McBurney, M.D., President of the Council of the Alumni of the College of Physicians and Surgeons of New York; George C. Freeborn, M.D.; W. P. Northrup, M.D.; and B. Farquhar Curtis, M.D., *Prize Committee.*

THE VARIOUS CONGRESSES OF LEARNED SOCIETIES have begun their work in Paris. A Medical Section was opened on June 11th, under the presidency of M. le Dr. Leroy de Méricourt, and some interesting papers were read. Among them was one by Dr. Florain, on the curious subject of the "Action of Human Saliva on Plants," one by M. le Dr. Moreau on the "Contagiousness of Crime," and one by Dr. Motais on "Heredity and Myopia." Dr. Montessus tried to show a "frequency of metritis in young girls"—he might have been in better business. Dr. Fabre presented a lengthy treatise on the "Hygiene and Diseases of Miners." M. Guelpa communicated the results of a study of tetanus.

CURES FOR THE OPIUM HABIT IN CHINA.—Dr. A. P. Peck writes in the China *Medical Missionary Journal:* "As no one is aware of the extent of the traffic in opium among the Chinese, or of the use of it as an intoxicant, so no one knows the extent of the trade in opium-cures among the natives, or of the demand for them by opium-users. The writer has met with frequent instances of breaking off the opium habit by smokers, both by force of will without the aid of medicine, and also in connection with the use of some native remedy prepared for the purpose. There are, doubtless, hundreds of such formulæ scattered through the country, jealously guarded by the owners, or only transmitted to a favored few. But besides these, there are large dealers in this line; there is at least one firm dealing in nothing but anti-opium pills, which has branches in every province of the Empire. The account of their operations reads like the record of some of our great Western houses. Their employees are numbered by hundreds, and their advertising bills foot up into a surprising number of thousands of taels. There is said to be hardly a mart in the Empire, from the small village fairs to the largest '*huis*,' where their posters cannot be found."

A NEW HEART-POISON was at the June 17th sitting brought to the attention of the Academy of Sciences by Dr. Arnaud, of the Museum, already known for his researches on ouabaïne and strophanthine. The active principle there shown in fine colorless crystals has been by him extracted from "tonguin," an ordeal poison of the Madagascar natives, and named tonghinine, from the botanical name, *Tonghinia toxifera*, of the plant producing the substance. A limited number of physiological experiments instituted by Dr. E. Gley, show the new chemical to be very poisonous, and to act on the heart, much after the fashion of ouabaïne and strophanthine. The resemblance will astonish no one, considering that tonghinia belongs, like the plants furnishing these, to the Apocyneæ family.—*Therapeutic Gazette.*

ANOTHER DISCOVERER OF THE MICRO ORGANISM OF CANCER.—Dr. Thoma, of Dorpat, in a recently published paper, claims to have discovered singular microbic organisms in the epithelial cells of carcinomatous tumors. The observer found small cell-like structures in the epithelial nuclei of carcinomata which differed so materially from all known kinds of cells that he felt compelled to classify them among the parasitic organisms. These microbes, for which thus far no pathogenic claim has been extended, are one-celled organisms measuring four to fifteen micro-millimetres in diameter, and can be seen distinctly with the aid of hæmatoxylin, safranin, eosin, and alum-carmine. They consist of protoplasm and a nucleus, have a regular round or oval form, and show a strong refraction of light. Thoma has repeatedly seen them single or in clusters of four to six embedded in the epithelial nuclei of carcinomata of the breast, of the stomach, and the intestinal tract. No pure cultures, nor other experiments which might serve to determine the exact nature of these microbes, have thus far been reported by Thoma.—*Therapeutic Gazette.*

GLYCERINE IN DYSPEPSIA.—Dr. J. A. Pollard claims (*Therapeutic Gazette*) that glycerine, in drachm doses, will be found most valuable in preventing stomach troubles in convalescence from debilitating diseases; that it will often cut short an attack of indigestion, and that it will prevent and cure a large proportion of cases of "summer diarrhœa" of children. It will also to a great extent control the vomiting of pregnancy.

THE SMALL-POX SCARE, which caused so much excitement at Castle Garden last Sunday, on investigation proved to be a case of measles.

# Society Reports.

## AMERICAN NEUROLOGICAL ASSOCIATION.

*Fifteenth Annual Meeting, held at Long Branch, N. J., June 26 and 27, 1889.*

FIRST DAY, JUNE 26TH—MORNING SESSION.

DR. E. C. SEGUIN, PRESIDENT, IN THE CHAIR.

DR. MORTON PRINCE, of Boston, presented a paper on

### MALARIA AS A CAUSE OF DEGENERATIVE DISEASES OF THE SPINAL CORD.

He spoke of the frequency of tabes and other spinal degenerations in cases which also presented a history of malaria. The first case he had recorded was one of locomotor ataxia with typical tabetic crises before each malarial chill. Another had gastric crises regularly once monthly; and another, crises beginning with rigor and followed by diarrhœa, this occurring every three weeks. The latter case had been diagnosticated as malaria by the family physician. Altogether the author reported in detail six cases showing the coexistence of tabes with malaria, and six cases where the malarial history was associated with disseminated sclerosis. Besides these he had notes of three other cases of multiple sclerosis, two of locomotor ataxia, and one of lateral sclerosis with a similar relation. Generally the malarial poison was present in the system previous to the development of spinal symptoms. He pointed out coincidences in the course of syphilis and malaria, such as the slowness of action of the poison and amenability to treatment; and also called attention to the relation of the syphilitic virus to tabes. He had found but little to support his etiological theory in literature. Erb, following Schulze, had stated that tabes may occur as a sequel to intermittent fever. Tuczek had proven that tabes could be caused by the ergot parasite. Many nervous disorders are undoubtedly due to malaria, such as neuralgias, anæsthesias, severe psychoses, etc. He alluded to the deposition of pigment in the brain in some cases of pernicious malaria. It would be very important for many army pensioners if it could be definitely determined that tabes and sclerosis might be sequelæ of malaria.

DR. N. E. BRILL said that his attention had never before been directed to the possibility of such a relation, but he thought the details presented were rather too meagre for an absolutely correct decision to be made in the matter. As neuritis and malaria were frequently associated, possibly some of these spinal cases might be coincident in the same manner. Both malarial and cord disorders are very common.

DR. L. C. GRAY saw no reason why the malarial poison should not cause spinal diseases. We do not yet know the exact character of the poison. But there is a sort of periodicity in many spinal and cerebral disorders, as well as in peripheral nervous affections, which is often as marked as that of fever and ague. He had noticed this particularly in intracranial syphilis. Some of these neuropathies were even relieved by quinine, as he had observed in cases of tabes. When we speak of latent malaria and rest our diagnosis merely upon periodicity, there is danger of error. If Laveran and Councilman were right in their discovery of the malarial germ, this should be looked for in such cases as the author had described in order to corroborate with certainty the diagnosis. Improvement or recovery under the use of quinine was no criterion.

DR. E. C. SPITZKA saw nothing in the nature of the case to forbid an etiological association between malaria and cord disorders, but he agreed with the preceding speakers that sufficient proof of such relation had not been adduced. To show an etiological significance, it was necessary to present absolute and intrinsic proof of it. If it could be shown that, as in syphilis, there were at the time of the malarial attack nervous symptoms, it would be a different matter. In the secondary fever of syphilis there was absence of the knee-jerk. Most nervous symptoms in malaria were of a neuralgic character. The anæsthesias differ from those of tabes. It had been found that pigmentary thrombosis and embolism were the most frequent causes of serious nervous disturbances in malaria. He believed, however, that, like any other cachexia, antecedent malaria might predispose to spinal affections. He had observed a case of paretic dementia of the tabetic type which was probably influenced etiologically by severe malaria.

DR. H. M. LYMAN, of Chicago, could recall but two cases where it had been intimated to him that the origin of tabes had been malarial. In one he traced the actual cause to a subacute spinal meningitis coming on after exposure to wet and cold. The other case, instead of being true tabes, had proved to be a rheumatic neuritis. He had in his experience seen nothing to support the idea of a malarial etiology in tabes. A complete and perfect history, together with a microscopical examination of the blood, should be required for an indisputable diagnosis of malaria.

THE PRESIDENT could not recall a single case of tabes or multiple sclerosis which presented any relation to malaria.

DR. PRINCE thought there could be no question as to the correctness of diagnosis as regarded the nervous symptoms in his cases; and as to the antecedent malaria, all of his cases were men who had been in army service, and he had documentary proof of their having suffered from that poison, in the shape of government records. The really doubtful question was whether the malarial poison still existed in the system at the time of the development of spinal disorders. In some of them there was evidence of its persistence in the shape of typical malarial rigor and pyrexia. He did not consider his etiological explanation decisive, but merely suggestive.

DR. SPITZKA thought that there were many cases of nervous disease owing their origin to exposure during the war which were contemptuously rejected by the Pension Bureau. It seemed to him that the Association ought to call the attention of the Government to the great injustice which might be done.

THE PRESIDENT, although once an army surgeon, and therefore prejudiced in favor of the soldiers, had been, on the contrary, struck by the vast number of fraudulent nervous cases which were awarded pensions.

Dr. W. M. Leszynsky, of New York, was then elected to active membership, and Mr. Victor Horsley and Dr. David Ferrier, of London, were elected to honorary membership. The resignation of Dr. A. D. Rockwell, of New York, was accepted.

---

AFTERNOON SESSION.

DR. B. SACHS, of New York, reported a case of

### NUCLEAR OPHTHALMOPLEGIA WITH POLIOMYELITIS (POLIOENCEPHALITIS SUPERIOR AND POLIOMYELITIS).

The relation between these two forms of disease, which had been suspected by Hutchinson, Mauthner, and others, was proven by this case. But one other was on record, that of Seligmuller. The history of the patient was, briefly, that a ptosis of the right eye gradually developed, followed after a few months by ptosis of the left eye also, and soon after a paresis of all the external ocular muscles of both eyes appeared. This resulted in almost absolute fixation of the right eye, but left a slight inward and upward movement of the left. There was immobility of the left pupil to light, but not to accommodation. The right could not be examined because of corneal opacity. During the development of this nuclear ophthalmoplegia,

a subacute poliomyelitis affecting the entire right leg supervened. There was now marked atrophy of the entire right leg. The knee-jerk was lost on both sides. There were no sensory disturbances. There were no tabetic symptoms, and the patient's condition was normal in all other respects. This case proved that the affection of the nuclei in the floor of the third and fourth ventricles was due to the same pathological process which gives rise to poliomyelitis when it affects the gray matter of the cord.

Dr. Spitzka said the report of the case had been so complete, and there being but one other such case on record, it did not admit of either criticism or comparison. He referred to Thomsen's case of unilateral nuclear paralysis, where there was a gummatous infiltration on both sides, and the explanation of which was to him quite impossible.

Dr. Sachs asked if fibres could be traced up through the ciliary nuclei.

Dr. Spitzka answered in the affirmative, and made black-board drawings illustrative of their course.

Dr. W. N. Bullard, of Boston, then presented, for Dr. J. J. Putnam, a skull which was a remarkable example of

HYPEROSTOSIS CRANII.

The case had been reported to the Association two years ago. The patient was a woman, thirty-one years of age at death. The chief symptoms were headache, broadening of the head, dropping out of the teeth, loss of hearing, vertigo, beginning gradually some years ago. There was extreme exophthalmos. There were no retinal changes. Extensive pachymeningitis was discovered at the autopsy. There was thinning and atrophy in parts of the skull. The orbital cavities were greatly diminished in size. Virchow considered hyperostosis cranii due to inflammatory changes. In this case, probably, the inflammation originated at the ear. Dr. Putnam had a patient now with similar symptoms, in whom the exostoses were first noticed in boyhood, and desired the opinion of members as to the justifiability of removal of certain exostoses for the relief of pain. Dr. Bullard himself thought it might be difficult to determine which of the exostoses produced the pain. Some of the exostoses were very diffuse, and the operation might have to be extensive.

The President believed that the pain would be more apt to originate from basal lesions, possibly dural inflammation about the issuing nerves. The jaw in this case was interesting because of its senile conformation and angle, despite the youth of the patient.

Dr. W. N. Leszynsky, of New York, read a paper entitled

SPONTANEOUS DEGENERATIVE NEURITIS OF THE BRACHIAL PLEXUS.

The patient was a laborer, aged thirty-eight. He first had pain in the left shoulder, shooting down the arm, which was ascribed to exposure to wet. There was then no involvement of the shoulder-joint and the motility of the arm was unimpaired. All the muscles reacted well to faradism, except the deltoid, which was atrophied. There was no sensory disturbance, but there was pain on pressure. Gradually other muscles became paralyzed, until a large number of the arm-muscles were useless. The paralysis was accompanied by pain so excruciating that the patient could not sleep at night. A feeling of numbness extended from the shoulder down the arm over the radial distribution, and a gradual anæsthesia and analgesia supervened throughout the same area. The faradic excitability disappeared, and there was galvanic hyperexcitability. Then he began gradually to improve, and will ultimately recover. The case was remarkable in its severity, in its idiopathic origin, and in the escape of the median and ulnar nerves from the inflammatory process. Not more than one case had, to his knowledge, been found in literature.

Dr. Prince thought it would be difficult in the early stages of such a case to distinguish it from progressive muscular atrophy of the shoulder type. He recalled a case of his own in which there was every reason for considering it to be neuritis. It began with cramps such as are observed in writer's cramp, and it was several years before other symptoms proved the case to be one of progressive muscular atrophy. The most common cause in such cases as the author's was traumatic arthritis, but generally the results are slight.

Dr. W. R. Birdsall had seen this case before, and was impressed with the idea that it might be a periarthritic affection, but the author's careful study of the case seemed to exclude this. He recollected that at that time there was some anchylosis of the shoulder-joint in the case.

The President considered the study of the differing resistances in the healthy and diseased arm made by the author interesting, and asked if any member had had experience in such measurements.

Dr. Gray had noticed much variation in resistance in many of his patients from day to day.

Dr. Starr had measured the resistance in Basedow's disease, and had found it to vary within a thousand ohms, in the same cases, from time to time. Electricity was diffused through muscular better than any other tissue. The chief resistance was in the skin. Probably but little of the current permeated nerves, and hence alterations of nervous tissue would not have much to do with the variations mentioned by the author.

Dr. G. M. Hammond stated that it was well known that the resistance differs from day to day in animals. He asked if in this case it had been measured for a number of times, and was answered that eight trials had been made.

Dr. Birdsall thought the question of resistance had little to do with our study of disease. It was easy to explain the numerous variations by the wide differences in vascularity and moisture of the tissues at different times. It might be due in this case to paralysis affecting the physical condition of the tissues. The saturation of the epidermis by perspiration would explain the variations mentioned by Dr. Gray. He had made measurements in cases of Basedow's disease some time ago, and believed the diminished resistance found due to the moisture of the skin. It could not depend on dynamic conditions in the nervous system, but was purely a matter of physics, about which there was no great mystery.

Dr. Gray said the explanation by moisture of the skin was not applicable in his cases. The differences which he had observed were not owing to the humidity of the atmosphere, although atmospheric conditions might possibly induce dynamic changes in the body.

Dr. Sachs pointed out that on one day the author's case showed 580 ohms increase on the diseased side, and on another day 1,170 ohms increase on the sound side. Such variations evidently had little to do with the pathological process in the patient. Eulenberg had measured the resistances in cases of paralysis agitans and of Basedow's disease, but without any practical results. As such measurements were very complex, they required exceedingly great care.

Dr. Prince objected to the use of the palm of the hand for precise experimentation, owing to the great variability of the thickness of the skin, and consequently of the resistance. He thought the forearm ought to be used.

Dr. Leszynsky had not brought forward the question of resistance in this case as a diagnostic symptom. It was increased in the affected arm at every examination. With subsidence of the symptoms the resistance gradually diminished, but there was a difference between the sound and morbid side throughout the disease. As to the question of moisture, there was excessive perspiration upon the paralyzed arm, while the normal arm was dry; in spite of which, the resistance was greater upon the former. He

thought it better to place the electrode upon the wrist than in the hand. There was no antecedent traumatism in the case; the roughening of the shoulder-joint was the result of the paralysis.

Dr. M. Allen Starr, of New York, then presented a specimen of an

INTERPEDUNCULAR MYXOSARCOMA.

It lay in the middle cranial fossa in the median line between the crura cerebri, which it separated. It extended into the lateral ventricles, separating widely the caudate nuclei and optic thalami. The patient was a male, aged twenty-one months at death. At the age of thirteen months, in October last, a lateral nystagmus had been observed in both eyes, varying from time to time. Drs. Knapp and Roosa found a slight pallor of the optic disks, which they considered normal. Later exophthalmos developed, gradually increasing until death. Convergence of the eyes was impossible, although no paralysis of a cranial nerve was discoverable. The reflexes of the iris were lost. Toward the middle of April, this year, the child became unable to walk. The knee-jerks were exaggerated, there was ankle clonus, and typical spastic rigidity. Finally, the back could not be held up, and later the head could not be supported. There was gradual emaciation. There was no apparent headache. From time to time the scalp was congested. About this time the pallor of the optic discs indicated atrophy. There was no blindness, no hemiopia, no aphasia, as far as could be ascertained, in so young a child. Toward the middle of May ataxia of the arms developed, but without loss of muscular power. June 8th, vomiting and Cheyne-Stokes respiration came on, and the child died in nine hours. The diagnosis of tumor had been made, but the question of localization was of great interest. Nystagmus was not a localizable symptom, but had been found most frequently in lesions of the corpora quadrigemina. The exophthalmos indicated intracranial pressure; the gait disturbance led one to think of a cerebellar lesion; while the ataxia of the hands pointed to a basilar trouble affecting symmetrically either the pons or the medulla. The question of operative interference had been considered, but he had opposed that proposition because of the difficulty of localizing the tumor. The autopsy proved that the pons was not even pressed upon, and that the cerebellum was normal. There were twenty ounces of fluid in the ventricles. He would ask if there was any localizing value in nystagmus or exophthalmos, and what was the probable cause of the ataxia.

The President, in referring to the question of ataxia, recalled a case of remarkable bilateral ataxia, with optic atrophy, where a large interpeduncular tumor was found between the crura. He thought such ataxia was to be accounted for by pressure upon the motor tracts or motor nuclei. To him the most puzzling feature of Dr. Starr's case was the absence of blindness. As to the nystagmus, it had as yet, in his opinion, no localizing value. He had seen two cases with lesions of the quadrigeminal bodies, but without nystagmus.

Dr. Leszynsky said the child may have had only central vision, which might explain the presence of nystagmus; but Dr. Starr answered that the visional fields were normal.

Dr. Sachs was reminded of Meynert's case of tumor in both optic thalami, with ataxia similar to that of Dr. Starr's case. He thought the thalami might have been pressed upon in the latter, but still was not sure that that would cause the ataxia. He considered nystagmus very frequent in many central disorders of children.

Dr. H. M. Lyman referred to a case he had seen recently of defective cerebral development in a child where there was also nystagmus.

Dr. Gray asked how a diagnosis of intracranial tumor had been made so early in this case, and was answered that the diagnosis had not been made until all the symptoms described had made their appearance.

Dr. Hammond thought ataxia depended upon injury to the optic thalami or corpora striata, and referred to a case of Weir Mitchell's in which there was a remarkable unilateral ataxia, with a lesion of the optic thalamus and corpus striatum upon the opposite side.

Dr. Leszynsky saw a child, several years ago, with well-marked nystagmus, which disappeared in the course of time. There was no discoverable cause.

The following gentlemen were then elected to active membership: Dr. C. Eugene Riggs, of St. Paul, Minn.; Dr. H. S. Upson, of Cleveland, O.

---

Second Day, June 27th—Morning Session.

Dr. E. C. Seguin, President, in the Chair.

Dr. George W. Jacoby, of New York, opened with a paper entitled

A CONTRIBUTION TO THE STUDY OF ANÆSTHETIC LEPROSY, WITH SPECIAL REFERENCE TO PARTIAL SENSORY DISORDERS.

The points to which particular attention should be paid in all cases were the electrical excitability of the muscles, the condition of the reflexes, the presence or absence of fibrillary twitchings, and the condition of sensation. Upon these data depended the diagnosis between anæsthetic leprosy and syringomyelia, as well as that of the central or peripheral localization of the leprous process. The conclusions arrived at by the author from the analysis of his own and other cases were that the differential diagnosis between the two diseases could not always be made; that partial sensory disorders are not characteristic of syringomyelia, but may occur in anæsthetic leprosy as well as in purely peripheral affections; and finally, that a differential diagnostic point between central and peripheral loss of temperature sense may lie in its complete loss in the one case and its partial loss in the other.

Dr. Starr said that the same question as to the differential diagnosis between syringomyelia and anæsthetic leprosy had only recently occurred to him. Three weeks ago he had seen a case, with Dr. Prince A. Morrow, of New York, in which there had been a gradual onset of an atrophic and anæsthetic affection of the right arm. He came from the Sandwich Islands and had been exposed to leprosy. There was anæsthesia to temperature and pain, but not wholly to touch, along the hand and part of the arm. There were three small reddish-brown spots on the arm, which Dr. Morrow considered leprous in character. The idea of syringomyelia at once occurred to him, but the history of exposure in a leprous country sufficed to make anæsthetic leprosy at least the more probable nature of the disease; but without such history it would have been almost impossible to make the diagnosis. As to the matter of partial loss of sensation in the cases of multiple neuritis and beriberi he had seen, the sensory loss was complete, with the exception, however, of muscular sense.

The President remarked that he had now under observation a case of leprosy, but had as yet made no careful examination of the temperature sense. His case illustrated the ease of diagnosis at an early period, when confusion with syringomyelia could not occur. The patient had a wine-colored eruption on the entire left leg and part of the thigh, the foot being free, and there were three or four similar spots on other parts of the body. There was distinct analgesia and some anæsthesia in these areas, but there was no paralysis or atrophy. The patient had come from the Sandwich Islands. The well-defined limitation of anæsthetic areas showed that it could not be neuritis. Of late the anterior leg muscles had become paretic, but there was no reaction of degeneration. The left hand was beginning also to manifest similar symptoms. There were no ulcers.

Dr. C. K. Mills had seen two cases of leprosy. He thought the author's point with regard to partial sensory disorder very interesting, but he did not see why there

should not be partial disturbance also in neuritis, and, in fact, in traumatic neuritis it was quite frequent. The nature of the sensory disturbance depended upon the extent of the injury to the nerve. In ordinary multiple neuritis it might be true, as Dr. Starr insisted, that there was complete loss of sensation, through destruction of all the sensory fibres. He did not see, however, why the sensation to cold should not be injured as much as any. It should be borne in mind that in all infectious diseases attacking the nervous system there was a tendency to seize upon the central as well as the peripheral portions at the same time.

Dr. Gray agreed with the last speaker as to partial sensory disorders met with at times in peripheral neuritis. He had observed it also in multiple neuritis, where, for instance, there was impairment of touch and temperature sense, yet the pain was excruciating. He did not see that it was easy to diagnosticate syringomyelia, and Wichmann and Starr had given no rules for diagnosis in their pamphlets. He believed that no one had made a diagnosis of syringomyelia in life.

Dr. Starr stated that Schulze had made the diagnosis in three cases, which had been substantiated by autopsy. The points for diagnosis were the general conclusions drawn from a study of collected cases. Anna Baumler had brought together one hundred and sixteen cases, to which thirty or more had since been added.

Dr. Gray thought these diagnostic points would apply to many other spinal lesions.

Dr. Birdsall had had similar ideas to those of Dr. Gray as regarded the diagnostic indications in syringomyelia until he had read Roth's collection of cases. In a certain number of such cases there were clinical pictures differing altogether from other spinal lesions and from peripheral neuritis. Disturbance of the temperature sense was the particular characteristic. Still the testing of this sense had been constantly neglected in studying other spinal cases, and it was possible that it might often be disturbed in other spinal disorders. It was hard to see how any other lesion could produce precisely the same symptoms as those of syringomyelia. It was a question whether tracts for temperature and pain could be localized in the cord. Peripheral nerve lesions might cause injury to some sense fibres and not to others, although generally all are injured, particularly where the inflammation is truncal in character. There might be partial sensory disturbance in dermal forms.

Dr. Gray said it was easy to localize disease in the anterior cornua, in the lateral and posterior columns of the cord, but the diagnosis of central lesions was very difficult. The fact that, out of one hundred and fifty cases of syringomyelia, only three had been diagnosticated during life, proved the truth of his assertion. The diagnostic suggestions given were therefore empirical. The presence or absence of temperature sense had not been sufficiently tested as yet. How would one distinguish a chronic central myelitis?

Dr. Birdsall stated that central myelitis began acutely, and thus differed from the slow advance of syringomyelia.

Dr. Mills thought the question of partial sensory disorder most interesting. But he thought that there would be more apt to be partial disturbance in a truncal neuritis than in a dermal.

Dr. Peterson asked the President if the tendon reflexes were exaggerated in his case of leprosy, and was answered in the affirmative. He had asked this because he had recently read an interesting study of the reflexes in anæsthetic leprosy made by Dr. Suzuki, of Tokio, and published in the *Sei-a-Kwai Medical Journal*, in which there was an analysis of seventeen cases. One had normal reflexes, while all the others had increased tendon jerks, and in some of the cases there was even ankle clonus. The conclusions arrived at by the author were similar to those of Dr. Jacoby.

The President called attention to the fact that so many cases of leprosy were now being continually imported into the United States. It seemed as if the country were threatened with its domiciliation. It was a question whether it was not the duty of physicians having such cases to report them to the authorities.

Dr. Sinkler mentioned the recent presence of two cases in Philadelphia. The physician in charge had been fined by the Board of Health for not reporting them.

Dr. Prince wondered at the manner in which leprous patients were allowed to go about, and thought also that the attention of the authorities ought to be called to the disease, and reports to the Boards of Health ought to be required.

Dr. Gray knew that in the East, where the disease is prevalent, isolation is practised. He wished to know what the actual danger of contagion was.

Dr. Brill said that the attention of the New York Board of Health had already been called to the matter.

Dr. Jacoby, in closing the discussion, said that Schulze was altogether too positive in his assertions. This author went so far as to contend that cases of leprosy where cavities had been found in the cord were not leprosy at all, but syringomyelia. As for himself, he thought a central lesion probably often exists in this disease, although it is well known that the essential pathology lies in a truncal neuritis. A simple dermal neuritis could not be assumed in leprosy. In his case, for instance, the indurated and swollen ulnar nerve could be distinctly felt. He did not agree with Dr. Gray, that the diagnosis of syringomyelia could not be made. The only danger lay in mistaking it for leprosy. He had only last evening come across a work of Suzuki mentioned by Dr. Peterson, but had noticed the identity of the conclusions of that author with his own, although they were reached from different points of view.

Dr. F. X. Dercum, of Philadelphia, then presented two contributions entitled, respectively,

A DESCRIPTION OF TWO CHINESE BRAINS,

and

A NOTE ON THE PLI DU PASSAGE INFÉRIEUR INTERNE IN THE HUMAN BRAIN.

He exhibited the brains described. Dr. Mills had made a morphological analysis of one in 1886, and descriptions of three Chinese brains had been added to literature by Moritz Benedikt. The six brains thus far analyzed exhibited unusual complexity, due to excessive sinuosity of the gyri, and a tendency to excessive transverse fissuration. The frontal lobes were especially large and complex. There was unusual confluence of fissures, indicative of a low degree of development, such as is often seen in the negro's, and sometimes in the white man's, brain. There was unusual length of the parallel and Sylvian fissures, and eversion of the orbital and temporal lobes.

Dr. Mills said that it was very important to keep adding to our morphological descriptions of such brains, until accurate deductions could be drawn from a very large number.

Dr. Spitzka stated that the dictum that a tendency to confluence of fissures indicated a low type of development, was not accepted by most anthropologists. The more brachycephalic the skull the greater was the development of transverse secondary folds. The elephant, which stands among the highest of mammals, had a broad skull and a tendency to confluence of fissures. The Chinese were not low in development. The internal pli du passage in the negro and idiot was significant only when the general cortical development was poor. The real cause of the location of the chief sulci lay in the inherent architecture of the brain, and was due to the arrangement of groups of cells and fibres; but the secondary and tertiary sulci might be influenced by other factors, such as the course of vessels. While we might never be able to localize the higher functions of the mind, there was something in the physiognomy of the Chinese brain which struck him as differing altogether from that of the Caucasian. But it was not the same

difference as was noticeable between the negro and Caucasian brains. The peculiar moral attitude of the Chinese pointed to some relation between the structure of their brains and the character of their minds. Still he had observed a great difference between these two Chinese brains, and there was no feature in them which might not be reproduced in the Caucasian brain.

DR. DERCUM had not wished to imply that transverse fissuration was indicative of a low type, but thought the unusual confluence showed a lack of cortical development. He did not consider them brains of a low type, but many features such as were found in the brains of the negro and ape were found here also. The excessive sinuosity, however, indicated a higher cortical development. For instance, in one brain there were five well-developed frontal gyri.

DR. SPITZKA had the same idea as Dr. Dercum. As compared with the Caucasian brain, the Chinese was in some respects inferior, and in others exhibited a superabundance of gyri. He spoke of the resemblance between the negro and ape brains. The differences between the brains of the orang-outang and chimpanzee were greater than those between the brains of the chimpanzee and a human being. There was no uniform appearance of the ape's brain. Vogt and another had classified the human brain into three types—the Negro, Mongolian, and Caucasian—corresponding somewhat to the three lower types of the gorilla, chimpanzee, and orang-outang.

DR. M. ALLEN STARR, of New York, then read a paper entitled

THE PATHOLOGY OF SENSORY APHASIA, WITH AN ANALYSIS OF FIFTY CASES IN WHICH BROCA'S CENTRE WAS NOT DISEASED.

In all of these cases collected by the author some form of sensory aphasia was present, and in all the lesion lay in the posterior lower third of the brain. In seven of the cases there was pure word-deafness, and in these the lesion was limited to the posterior portion of the first and second temporal convolutions. In eleven cases there was pure word-blindness, and in these the lesions were found distributed either in the angular gyrus, the occipital lobe, the temporal convolutions, or the inferior parietal region.

In seven cases word-deafness and word-blindness were co-existent, although the use of language was not lost; and in these the temporal convolutions were involved, extending in some to the inferior parietal, angular, and occipital convolutions. The practical application of the localization of aphasia lesions is obvious, for the regions concerned in speech are especially accessible to the surgeon.

Another fact of interest is that it seems to be proven that there is no ideational centre. An idea may be impaired but cannot be wholly destroyed by a single cortical lesion. Thought, being regarded as the play of consciousness along association-fibres between sensory centres, cannot be localized.

DR. LLOYD had now a case of simple homonymous hemianopsia without psychical or word-blindness, and wished to know whether there was any diagnostic importance in this condition as to localization. Was there a preponderance of one hemisphere over another as regarded sensory memories of language?

DR. STARR said that the matter of psychical blindness had recently been discussed by Wernicke and another. A lesion affecting bilaterally both occipital lobes or the association tract produces psychical blindness, but a lesion along either tract itself does not cause this condition. Nine cases of psychical blindness from lesion of one hemisphere alone had been reported.

The election of officers for the ensuing year being then in order, the following were chosen: *President*—Dr. E. C. Spitzka, of New York; *Vice-Presidents*—Dr. Wharton Sinkler, of Philadelphia; Dr. H. M. Lyman, of Chicago; *Secretary and Treasurer*—Dr. G. M. Hammond, of New York; *Councillors*—Dr. Henry Hun, of Albany; Dr. C. L. Dana, of New York.

AFTERNOON SESSION.

DR. J. H. LLOYD, of Philadelphia, read a paper entitled

A LATER HISTORY OF A CASE OF FOCAL EPILEPSY, FOR WHICH TREPHINING AND EXCISION OF THE MOTOR CENTRES WERE PERFORMED.

Full details of the case had been recorded at the last annual meeting of the Association. At that time but three months had elapsed since the operation, and Dr. Ferrier, of London, had stated in a discussion that the time was too short for a decisive result as to the usefulness of the operation. Now that more than a year had passed, further details could be given. Before the operation the patient had had many seizures daily. There was no fit for four months after the operation. Since that time, however, there had been some ten seizures in nine months.

DR. SPITZKA said there was a minority, but a powerful minority, of clinicians and physiologists who hesitated to accept the dictum that spasms were always of cortical origin when clonic in character and local in manifestation. There were well-authenticated cases of spasms, such as are generally described as cortical, which undoubtedly had their origin in the pons or medulla. He therefore thought it premature to advise surgical procedure when there was still doubt as to the position of the convulsive centre. He was of opinion that the seat of irritation in the great majority of cases of epilepsy was in lower centres, such as Nothnagel's convulsive centre.

DR. MILLS mentioned the case of a man subject to unilateral convulsions beginning in the hand. There was a scar upon the head, and trephining was done at this spot in order to relieve severe pain, probably due to trigeminal irritation in the scalp or dura. This operation relieved the pain, but caused the Jacksonian epilepsy upon the other side. The operation was repeated in the same spot, the membranes and cortex being removed to some extent, and with great success. It was an apparent illustration of the fact that convulsions may occasionally be the result of operations themselves.

DR. DERCUM had seen the same case, and stated that the dura was not opened in the first operation. At the second trephination the membranes were found united. There was a pachymeningitis. The patient had surgical epilepsy. Six months elapsed between the operations.

DR. LLOYD said it was a question whether one could have localized epilepsy from irritation of lower centres, as Dr. Spitzka had intimated. He had always held the idea that such spasms were of cortical origin. In the case he had just described the absence of fits for four months led him to believe that he had removed the parts concerned in their manifestations. He had been hopeful of the efficacy of this method in the relief of such a disorder, and was not yet willing to give up the idea that something may be accomplished in this way. He thought it would be justifiable to operate again in this same case.

DR. SPITZKA asked if the cortex removed had been examined microscopically, and what was the pathological condition found.

DR. LLOYD answered that the microscopist had reported atrophy of the cortical cells.

DR. SPITZKA remarked that atrophied cells could scarcely be very potent in the production of epilepsy.

DR. LANDON C. GRAY, of New York, then presented a paper upon

THE DIAGNOSTIC SIGNS OF MELANCHOLIA,

in which he called particular attention to the difficulty of diagnosis of simple melancholia at times. It was usually, when in mild degree, confused with neurasthenia. He had recently made a study of eighteen cases of this form, and pointed out what he considered the three cardinal symptoms, viz., depression, insomnia, and post-cervical ache. The last named he thought especially characteristic. This pain was sometimes neuralgic in character; at others, vague and continuous. Simple melancholia such

as this should not be confounded with neurasthenia, or melancholy states dependent upon hepatic or nephritic disease, or with non-typical forms of insanity.

Dr. H. S. Upson, of Cleveland, then read a paper in which he considered the relation between

MULTIPLE NEURITIS AND INFECTIOUS CEREBRO-SPINAL MENINGITIS.

Dr. Mills had first suggested the possibility of connection between the two. His own case was, briefly, as follows: A woman, aged twenty-seven, had intense pain and tenderness in the extremities, together with stupor and slight opisthotonos; no electrical examination could be made because of the extreme hyperæsthesia. She had had a multiple neuritis a year before, but recovered. The autopsy revealed congestion of the pia of brain and cord with marked serous effusion, and a microscopic examination of the ulnar nerve revealed interstitial inflammation there. In the opinion of the author, the nerve-trunk inflammation was not parenchymatous, but rather of the membranes, and was analogous to the process in the brain and cord; the nerve-fibres were secondarily involved. He had not looked for bacteria. He naturally felt interested in the case. He had had an autopsy on one of his own cases. Portions of nerves and sections of the brain and cord had been examined by Dr. Gray, of Washington, and this examination proved conclusively the association of neuritis with the cerebro-spinal meningitis.

Dr. Spitzka referred to the vacuoles in the author's sections, and said retarded lymph-outflow might be important in causing the death of tissue and the formation of gas-bubbles which these vacuoles must be considered to represent. He had noted, also, two bodies in the section larger than ordinary leucocytes, very delicately stained, which the author should have carefully delineated.

Dr. C. K. Mills, of Philadelphia, then gave an abstract of a paper by Dr. J. T. Eskridge, of Denver, on a

CASE OF ABSCESS OF THE BRAIN; OPERATION; DEATH ON THE NINTH DAY.

The patient had had typhoid fever. Two months later there was purulent inflammation of the middle ear, and not long after symptoms of brain-irritation followed, such as headache, delirium, persecutory delusions, together with paralysis of the right hand and right angle of the mouth. The skull was trephined over the face and hand centres, and a purulent inflammation was found under the dura. The wound was then dressed, and the patient died nine days later. A wide-spread suppurative meningitis was found at the autopsy. Dr. Mills thought the case of great practical value. He thought trephining should have been performed in two places, at the centre which had been properly localized and also over the mastoid region where the inflammatory process had originated.

Dr. B. Sachs, of New York, presented a paper on the

PERONEAL FORM OF PROGRESSIVE MUSCULAR ATROPHY.

The author reiterated his statement of last year that this form was closely related to Duchenne's type. He gave very full details of the cases of two brothers that had recently come under his observation through the kindness of Dr. Gibney. The boys were thirteen and ten years of age. There was a gradual development of double club-foot in both at the age of five years, followed by an atrophy proceeding upward, beginning in the leg and toe muscles and spreading to those of the thigh, in one case also involving muscles of the upper extremities. The knee-jerks were present. In one there was general anæsthesia; in the other, paræsthesia. There was full degenerative reaction in some of the muscles in one boy; partial, in the other. The progressive wasting rendered treatment of this form of club-foot less satisfactory than that of congenital cases. He would suspect this peroneal form in all cases where acquired club-foot was associated with progressive wasting of the leg muscles, and particularly if heredity or family occurrence of the disease could also be established.

Dr. Sinkler could recall several similar cases; one, in particular, of two brothers. But doubtless more would be seen if careful attention were paid to the matter.

Dr. Birdsall did not think the presence of knee-jerk so important a diagnostic point as the author seemed to regard it. He had seen a few cases of old poliomyelitis where the paralysis and atrophy were below the knee, and yet the knee-jerks were quite active on both sides. It could not therefore be an essential point in diagnosis.

Dr. Bullard had also observed the presence of the knee-jerk in old cases of poliomyelitis.

Dr. Prince asked if the author had said that the absence of pseudo-hypertrophy was a diagnostic point between this form and primary myopathies, and was answered in the affirmative. He did not consider this true.

Dr. Spitzka asked if the symmetry and the coincidence of time and intensity as shown in the photographs were always the case, and was answered in the affirmative.

Dr. Sinkler corroborated two of the speakers as to the presence of the knee-jerk in cases of old poliomyelitis, and cited an instance from his own experience

Dr. Gray objected to the division of progressive muscular atrophy into groups. Why should there be an arm type, a face type, a leg type? Such division might be carried out indefinitely. A more useful classification would be upon the pathology of the disease—a division into central, muscular, and peripheral nerve-lesions.

Dr. Sachs said he did not lay great stress upon the presence or absence of the knee-jerk. Yet in extreme atrophy of the vasti from poliomyelitis the knee-jerk was always absent; and if it were present, he should consider it a case of progressive muscular atrophy. He had himself tried to discard subdivisions as much as possible, but the present classification was a clinical necessity. A better might be made when the pathology is more accurately determined. At present there were spinal and non-spinal cases, but there was no certainty as regarded peripheral nerve cases.

Dr. Morton Prince, of Boston, then exhibited some microscopic specimens from the muscles of a case of

PSEUDO-HYPERTROPHY.

The patient was now twenty-eight years of age. The specimens showed a large quantity of connective tissue, hypertrophy of a few fibres, and great atrophy of many of the fibres. There was also great loss of striation, but no fatty or granular degenerations and no vacuolization.

The following papers were read by title: "A Series of Cases of Cerebral Hemorrhage of Unusual Interest," by Dr. J. H. Lloyd, of Philadelphia; The Histological Examination of Nerves removed for Trigeminal Neuralgia," by Dr. J. J. Putnam, of Boston; "The Pathological Anatomy of Chorea," by Dr. C. L. Dana, of New York; "Paranoia in Two Sisters," by Dr. Frederick Peterson, of New York.

The following new active members were elected: Dr. Hobart A. Hare, of Philadelphia; Dr. J. P. C. Griffith, of Philadelphia.

The meeting then adjourned.

In the evening a banquet was given by the Association at the place of meeting, the West End Hotel, at which some thirty members were present.

---

A Gargle in Quinsy.—Dr. W. M. Beck, of Kensington, Kan., writes: "In your 'Medical Item' column I notice that Sajous recommends guaiac as a gargle for early stages of quinsy. Chloral hydrate has been far more efficient in my hands; in fact, nearer a specific than anything recommended in the text-books. Three or four grains to the ounce of glycerine may be used as a gargle. I mention this because no reference is made by Ringer or other therapeutists to this fact. Its efficiency and *modus operandi* are at once apparent when we consider that it is locally antiseptic, astringent, and sedative."

# Correspondence.

## PERINEAL LACERATIONS.

To the Editor of The Medical Record.

Sir: I desire to call attention to some points considered by Dr. James K. King, in a paper entitled "Surgical Treatment for Lacerations of Perineum, with some Important Modifications," which appeared in The Medical Record of June 1st.

The paper would be a most valuable contribution were lacerations of the posterior vaginal wall limited to the median line, and were the wound resulting from his operation, which contains three rows of stitches, tolerably sure of uniting; but the contrary is usually true.

In studying the continuous support of the posterior vaginal wall, it is unphysiological to attribute any of this action to its muscles; then, as a consequence, connective tissue alone remains to be considered.

The connective tissue is liberally attached to the bony portion of the true pelvis, and is abundantly distributed through the posterior vaginal wall. The tissue becomes soft and yielding at parturition, and normally stretches at this time, without separation, so as to permit passage of the fœtal head. The head is moulded to the bony canal in its passage, which demonstrates that the connective tissue, during labor, is normally capable of stretching to the dimensions of the canal. Then when the posterior vaginal wall separates during labor, it is due to one or more of the three following causes: 1. Diseased connective tissue; 2, too great force brought to bear upon the posterior vaginal wall before its connective tissue is sufficiently softened; 3, scraping or tearing of the connective tissue from its attachment by passage of the fœtal head.

Cicatricial contraction is the disease most apt to affect the connective tissue. This must be a rare complication to labor, and can very seldom obtain in primiparæ.

Laceration of the posterior vaginal wall in rapid labor is caused by the exertion of too great force upon the connective tissue before it becomes softened. Scraping and grinding of the connective tissue of the posterior vaginal wall from its attachment have not before been recognized as a cause of the so-called "laceration of the perineum." Strong evidence exists, however, that this is true. The connective tissue attached to that portion of the ischium around and including the spine is the portion most subject to this grinding between the fœtal head and the bony canal. This is the location of many tears described under the heading of lateral lacerations. This location of laceration occurs usually in difficult and protracted labors, and in patients in whom the mobility of the pelvic bones has been diminished by age or disease; while in women before this has taken place, the laceration is more often median, occasionally including the sphincter ani, and seldom accompanied by any lateral separation.

Lacerations of the posterior vaginal wall are conveniently divided into the four following varieties: 1, Bilateral; 2, unilateral; 3, median; 4, mixed.

In the bilateral variety the fourchette, perineal body, and medio-recto-vaginal septum retain their normal dimensions; yet this laceration causes most suffering from lack of support. The vagina is relaxed; the portion of ischium around and including the spine apparently remains covered by periosteum and vaginal mucous membrane only. Rectocele exists as a result of the detachment of the ends of the connective-tissue band, as it were, which stretches across the pelvis in front and surrounds the rectum. The rectocele is obscured from view by the perineal body, but want of support to the rectal wall is felt by the patient while at stool, and recognized by digital examination when the abdominal muscles are contracted. The transverse perineal muscles, being separated from their attachment to the ischium, fail to perform their function of assisting in counteracting the increased pressure upon the anterior rectal wall during defecation, and thus allow this connective-tissue band to relax and double upon itself as the rectocele forms. Let it not be understood that the ends of the separated fibres remain free, for an adhesive inflammation takes place soon after labor, forming a weak attachment at a variable distance from their original location.

Cases are occasionally seen where the tear is nearly, if not entirely, limited to one side; all the physical signs are the same on one side in the unilateral as in the bilateral variety. To produce this, the laceration of tissue must be at or near the point of attachment, where the tissue easily becomes engaged between the ischium and fœtal head in its rotatory passage. This lesion strengthens the evidence in favor of this origin of laceration.

Median lacerations involve principally the vaginal outlet and occasionally extend through the sphincter ani. When the tear is extensive, the labor producing it must have been either rapid or instrumental. In rapid labors the fœtal head does not become firmly engaged in the bony canal. As a natural consequence, the fœtal head does not grind the tissues against the ischii in its rotatory passage, and, as would naturally be expected, the tissues remain uninjured at this point. The different varieties often exist mixed, one predominating.

Dr. King still continues to make the great error of attributing much of the uterine support to the perineal body. This function its anatomy and clinical history emphatically contradict.

While interne in the New York State Woman's Hospital I had the opportunity of observing in a large number of cases the effects of lacerations of the vaginal outlet, often including the sphincter ani, and also cases in which incisions had been carried down to the rectal wall; yet in none of these did any appreciable want of support exist.

The following case well illustrates the non-support of the perineal body: Miss W——, a number of years before being admitted to Dr. Bozeman's service in the New York State Woman's Hospital, had a cystotomy performed for the relief of chronic cystitis. The vaginal outlet preventing free escape of urine, it was incised down to the rectal wall; as this gave no relief an incision was made on each side of the rectum, exposing fully three-fourths of its surface. She had been in this condition either three or five years, as I recollect, before entering the hospital, yet no want of support existed, and she had been able to be up and around nearly the whole time.

Another strong clinical fact in oppostion to the old theory of the support of the perineal body can best be given in Dr. Emmet's [1] words: "We can realize that this is not true from the statement of any woman who is suffering from an extensive cellulitis, for she is unable to take a single step without feeling the force transmitted directly through the solid and inelastic tissue, which should aid in giving the most perfect support from below, if the perineum could exercise such a function." And as to the absurdity of such a belief, he says: [2] "It would be as rational to assume that a man's pantaloons were supported by the legs resting on the instep or foot."

But the posterior vaginal wall assists in the support of the anterior vaginal wall, which is a strong factor in determining the position of the uterus. When the length of the anterior vaginal wall is normal, the cervix is held so near the sacrum that it is difficult for the uterus to become seriously retroposed.

The anterior vaginal wall has other support besides the posterior vaginal wall, for cystocele never forms when the perineum is incised down to the rectal wall; and seldom, if ever, after deep median lacerations of the posterior vaginal wall. My impression is that cystocele, as a result of labor, is usually, if not uniformly, associated with lateral lacerations of the posterior vaginal wall; that is, the lateral laceration and the cystocele have a common cause.

[1] Principles and Practice of Gynecology, p. 365. [2] Ibid.

Both usually occur after difficult and protracted labor; or after the mobility of the pelvis has been diminished by age.

The anterior vaginal wall has its support from a band-like formation of connective tissue which stretches across the pelvis, and cystocele usually forms as a result of laceration of this tissue. This laceration may occur under the same conditions, in the same manner, and at the same time as does lateral laceration of the posterior vaginal wall.

A movable retroposed uterus, resulting from laceration of the posterior and, probably, of the anterior vaginal wall, seldom retains its normal position after the usual operations have been performed upon both of the vaginal walls, without the use of a pessary. This fact is entirely consistent with the fact that the anterior vaginal wall has support from connective tissue as described, and that cystocele is usually the result of leceration of this tissue. The more the connective-tissue support of the anterior vaginal wall is weakened, the more is the support of the posterior vaginal wall needed.

The direction of stitches as Dr. King describes it is the most rational for use in median lacerations only; and, were the resulting wound tolerably sure of uniting, it would be a most admirable operation in tears at the vaginal outlet. But why take the greater risk of union by first intention, and do the extra work, when the vaginal outlet can be as well built up with one line of sutures?

Dr. King's operation in lateral lacerations seems to me useless, as he apparently does not consider the folly of uniting and rolling up tissue never torn. One who has utterly failed to appreciate the teaching of Emmet would be likely to agree with Dr. King.

Emmet's operation does not fix the separated ends of connective tissue and muscles in their natural location, but practically accomplishes the same result by strengthening the union formed soon after labor, and by taking up the slack tissue.

Dr. King gives the following objections to Emmet's operation: 1. Stitches are passed transversely to important perineal vessels, causing swelling and pain. 2. Stitches passed in this manner draw down the posterior vaginal wall, "followed by the uterus," causing increase of the rectocele.

Dr. King evidently is not aware that the stitches in the lateral triangles in Emmet's operation are passed in a line curved downward and backward (in practically the same direction as Dr. King's "first stitch"), the last of which extend nearly to the skin, drawing the posterior vaginal wall forward and inward. This is the direction of the greater number of stitches used by Dr. Emmet in his operation on the vaginal outlet, as practised by him in the New York State Woman's Hospital, but not clearly stated in his "Principles and Practice of Gynecology."

That the procedure causes swelling is the best recommendation for the operation, as it demonstrates that it has a curative action upon the diseased blood-vessels which cause the "bearing-down pains." The abundant collateral circulation of the posterior vaginal wall prevents any danger from too great obstruction in the circulation, and the swelling does not interfere with union.

In none of a large number of these operations observed in the New York State Woman's Hospital can I recall the presence of sufficient pain to demand an anodyne. There is little cause for pain, since none of the sutures include the skin in ordinary cases.

Dr. King's ojection to the result of Emmet's operation, namely, the drawing down of the posterior vaginal wall, may be explained by his failure to appreciate the direction of the sutures, unless he attributes this action to the crown-stitch; but, as the point of support is above, the resultant traction elevates instead of depressing the posterior vaginal wall.

Dr. King's error, of attributing to Emmet's operation a drawing down of the uterus, is consequent upon his non-recognition of its true support.

Rectocele from lateral laceration cannot be increased by Emmet's operation on the vaginal outlet, except in the imagination of a misguided critic.

I doubt whether Dr. King's operation will cure any case of rectocele, as it is not clear that median lacerations cause rectocele. I cannot recall a rectocele from laceration at the vaginal outlet, and do not see how it could occur. The connective-tissue band, briefly described above, crosses in front of and surrounds the rectum. This band is not so tense as to make its rupture in the centre probable; and, if it did, would not the tissue surrounding the rectum prevent a rectocele? And if the rectum does not receive strong support from the sides and posterior surface, what supports it when the anterior wall tears for some distance above the sphincter ani, from within outward, as Emmet[1] describes?

Dr. E. C. Dudley does a modified Emmet's operation, which seems to be an improvement. He uses silkworm gut for sutures, which possesses all the advantages of the silver suture, and, in addition, is more easily applied and removed, and he has found that they may remain longer without producing suppuration.

Dr. Dudley introduces the first suture in the lateral triangles, after Emmet; ties it, and makes traction upon it upward and inward in the direction of the sulcus, while the next suture is being introduced and tied. The second and each succeeding suture are introduced under the same conditions; *i.e.*, while a suture is being introduced and tied, the one just before it is being firmly drawn upward and inward in the direction of the sulcus by means of a pair of Pean's forceps.

After all the sutures have been placed in the two sulci, the crown-suture is now introduced deeply through the lowest myrtiform caruncle on the patient's left, underneath the upper portion of the remaining denuded surface on the posterior vaginal wall, and is brought out through the opposite myrtiform caruncle. This suture, when tied, restores the annular hymen, unless the remains of that organ have been obliterated. The remaining sutures close the more external part of the wound, and make a median line of union out over the posterior commissure of the vulva toward the cutaneous portion of the perineum, and this union may reach nearly or quite to the anus. These last sutures, external to the remains of the hymen, should be introduced with the same method of traction used in the sulci, the traction being toward the meatus urinarius.

Dr. Dudley informs me that he has performed this operation in more than one hundred cases, and in no case has the posterior vaginal wall failed to come well up under the pubes. This failure, however, will sometimes occur when the sutures are introduced without this method of traction.

T. J. WATKINS, M.D.

Vol. 36, No. 5 NEW YORK, AUGUST 3, 1889 Whole No. 978

## Original Articles.

### THE RELATIVE GERMICIDAL VALUE OF THE SO-CALLED ANTISEPTICS.

BY JOHN E. WEEKS, M.D.,

ASSISTANT SURGEON TO THE NEW YORK OPHTHALMIC AND AURAL INSTITUTE, LATE INSTRUCTOR IN BACTERIOLOGY AT THE NEW YORK POST-GRADUATE SCHOOL.

IN a recent address made by a very prominent surgeon of this city, the statement was made that "we cannot to-day formulate a list of germicidal remedies as we thought we could five years ago." This is in part true; however, the investigations that are being made in this line are gradually bringing order out of chaos, and we are nearing a stage where the germicidal effects of remedial agencies will be definitely known. The object of this paper is to submit the results of investigations made to this end, and to render more complete a list of germicidal remedies submitted by the author, in a paper which appeared in the *Arch. of Oph.*, vol. xvi., No. 4, p. 375. The experiments (conducted for the most part in the laboratory of the New York Ophthalmic and Aural Institute) from which the conclusions following were drawn, were made with pure cultivations of pathogenic germs, and correspond very closely with what is known clinically of the effects of the remedies experimented with.

In the present stage of our knowledge, it is not necessary to urge the causative relation of bacteria to disease, to advance proof that the staphylococcus pyogenes is the essential factor in the production of a large portion of the suppurative processes, or that a certain bacillus is the active agent in the production of typhus abdominalis. These points have already been established by the able work of Ogston, Rosenbach, Koch, Eberth, Gaffky, and many others.

As our knowledge of the actual value of remedial agencies advances, it becomes more and more apparent that the agents that are of most value—I might say, that are of any value—in the treatment of infectious or contagious diseases, are those which, first, act directly on the pathogenic germ to impair its vitality; second, those which convert the pabulum on which the germ feeds into a condition which prohibits its development; third, those remedies that stimulate the general system and increase the antagonistic, or phagocytic power of the animal cells. To the first belong the germicides, to the second the germicides and antiseptics, and to the third, tonic remedies, either local or general, suitable alimentation, etc.

The line of investigation here reported is that of the effect of certain remedial agencies on the vitality of germs. It is an evident fact that any remedy, to be effective as a germicide, must be brought in contact with the germ in sufficient concentration, and for a sufficient length of time, to produce its germicidal action, and it is very desirable to know the time and concentration required by the various remedies. This knowledge is of great importance to the general practitioner, but is of greater value to the surgeon, and is quite different from the knowledge of the proportion of a germicidal remedy, contained in a substance suitable for the growth of germs, required to prevent their development. Remedies that prevent the growth of germs are not necessarily germicidal, as instance boric acid and desiccating powders; and although capable of retaining an aseptic condition in substances already free from germs, are of no value as disinfectants, and will not prevent the further development of the germs if their inhibitory presence is removed within the time of the natural life of the germ. For the purposes of surgical practice, in cases where the condition requiring operative interference has no connection with bacteria, simple aseptic solutions for the removal of blood, etc., the condition embraced under the general term of cleanliness is all that is indicated, and will in almost all cases produce good results; but in cases where the operator must deal with germ-infected tissue, a germ-destroying agent must be used to insure the best conditions for recovery.

The germs employed for making these investigations were the staphylococcus pyogenes aureus and the typhoid bacillus, and the results arrived at with these germs are applicable within very narrow limits to all pathogenic germs, if the spores (formed only by a limited number of bacilli) are not considered, as shown by the experiments of Koch, Sattler, Sternberg, and others. The staphylococcus pyogenes aureus was obtained by cultivations made from abscesses and eczema pustules, and their virulence tested by inoculations of the eyes of rabbits; the typhoid bacillus from cultivations at the Hoagland Laboratory. The methods employed for testing the various remedies were as follows: For liquids, an emulsion of a pure cultivation of the germ was made in sterilized water, into which sterilized platinum rods were dipped and immediately transferred to a solution of the remedy to be tested. After remaining in this solution for a certain length of time, sterilized nutrient agar, contained in test-tubes, was inoculated with the rods, the tubes placed in an incubator at a temperature of 37° C., and the effect of the solution on the vitality of the germs determined by their development or non-development. Powders and ointments were tested by intimately mixing a quantity of the germs with the powder or ointment, and after the desired time had elapsed, transferring a very small part of the mass to the sterilized food medium. The method employed by Koch, Sattler, and others, of immersing sterilized pieces of silk thread in an emulsion of the germs, transferring them to the liquids, powders, etc., to be tested, and then introducing them to the food medium, was only used in a few instances where the exposure was for a long time. In cases where the exposure is for a fraction of a minute, this method is faulty, since it requires an appreciable time for the remedy to reach the interior of the thread. Straight rods were employed, in order that the germs exposed should come in contact with the substance experimented with immediately.

Substances the names of which are marked with an asterisk (*) were experimented with two years ago, and the results reported in the *Arch. of Ophthal.*, vol. xvi., No. 4, 1887. The staphylococcus pyogenes aureus only was used in the first experiments. The staphylococcus pyogenes and the typhoid bacillus were used in the subsequent experiments.

*Bichloride of mercury. When a solution of the bichloride of mercury in distilled water is made, a precipitate forms on standing—usually of the mild chloride. This may be obviated by adding a small amount of sodium or ammonium chloride to the solution.

| | | | | | | |
|---|---|---|---|---|---|---|
| 1 to | 500 | destroys | vitality | in | exposures of | 10 seconds. |
| 1 to | 1,000 | " | " | " | " | 45 " |
| 1 to | 2,000 | " | " | " | " | 1½ minute. |
| 1 to | 4,000 | " | " | " | " | 2½ minutes. |

1 to 5,000 destroys vitality in exposures of 3 minutes.
1 to 10,000 " " " " " 5 "
1 to 20,000 " " " " " 12 to 15 minutes.

*Bisulphate of mercury. Soluble in about 1 to 7,000 of cold water (U. S. D.). 1 to 8,000 destroys vitality in exposures of four minutes. Very slightly irritating to mucous membranes.

*Biniodide of mercury. Solubility in water 1 to 40,000 (?). Saturated watery solutions destroy vitality in exposures of four days.

*Bromide of mercury. The saturated solution in water (very sparingly soluble) destroys the vitality of the staphylococcus in exposures of some days.

*Iodide of mercury (green iodide), not soluble in water.

*Yellow oxide of mercury. A saturated solution in water (very sparingly soluble) destroys vitality in exposures of two to four days.

*Red oxide of mercury corresponds with the yellow oxide in its antiseptic and germicidal properties.

Oxycyanide of mercury, highly extolled by Dr. Chibret (Soc. de Biol., Paris, 1888, p. 585) as a germicide, and placed by him about on a par with the bichloride, makes a very poor showing in my hands. It is quite readily soluble in water; 1 to 100 requires ten minutes' exposure to destroy the typhoid bacillus, and twenty to thirty minutes to destroy the vitality of the staphylococcus aureus.

* "The mild chloride of mercury is not soluble in water; however, when mixed with water in the proportion of 1 to 500, the ordinary preparations are germicidal to a low degree." No bichloride could be detected on testing this mixture.

*Nitrate of silver. In this salt we have an excellent germicide, the value of which does not appear to be recognized by the profession. Aside from the work by Ratincoff and Miquel, who determined that in the proportion of 1 to 10,000 it arrested putrefactive processes, little has been done with the nitrate of silver in an experimental way. We may assign this salt to a position near the head of the list of germicidal remedies, as the following shows:

1 to 10 destroys vitality in exposures of 4 seconds.
1 to 50 " " " " " 8 "
1 to 100 " " " " " 12 "
1 to 500 " " " " " 1½ minute.
1 to 1,000 " " " " " 4 minutes.

These experiments explain its great efficacy in the treatment of eczema, purulent affections of the eye, otorrhœa, etc.

Iodide of silver. Very slightly soluble in water. A saturated watery solution destroys the vitality of the staph. pyog. and the typhoid bacillus in exposures of ten minutes.

*Permanganate of potash. Readily soluble.

1 to 50 destroys vitality in exposures of 20 seconds.
1 to 100 " " " " " 1 minute.
1 to 200 " " " " " 5 minutes.
1 to 500 " " " " " 20 "

Not a very stable preparation.

*Potassium hydrate, 1 to 5, destroys vitality in exposures of five minutes.

Creasote from the distillation of birch-wood (Merck) is a very active germicide, and probably owes its good repute in the treatment of tuberculosis, chronic bronchitis, zymotic intestinal troubles, etc., to this property. The pure creasote requires an exposure of less than ten seconds to destroy the vitality of the staph. pyog. aur. and the typhoid bacillus. It dissolves in water in the proportion of about 1 to 250, and in this solution destroys vitality in exposures of thirty seconds.

1 to 400 destroys vitality in exposures of 5 minutes.
1 to 800 " " " " " 10 "
1 to 1,000 " " " " " 30 to 40 minutes.

The saturated watery solution is but slightly irritating to mucous membranes.

Creolin. Much has been written in praise of the antiseptic value of this product, from coal tar. The results of experiments here given show it to be inferior to carbolic acid.

Pure. Vitality destroyed in exposures of less than 10 seconds.
1 to 10 " " " " " 1 minute.
1 to 20 " " " " " 3 to 5 minutes.
1 to 40 " " " " " 10 minntes.
1 to 100 " " " " " 20 to 30 minutes.

Trichlor. phenol. Chief product of the action of chlorine on phenol; insoluble in water, soluble in oils and ether.

Five per cent. solution in olive-oil, exposure of four hours, failed to destroy the vitality of the staph. pyog. and typhoid bacillus.

1 to 10 in ether, destroys vitality in exposures of 10 seconds.
1 to 20 " " " " " 20 "
1 to 100 " " " " " 5 minutes.

Naphthalin. Obtained by distillation from coal tar; not soluble in water, but soluble in oil and ether.

Five per cent. solution in olive-oil failed to destroy the vitality of germs in exposures of four hours. Solutions in ether.

10 per cent. destroys vitality in exposures of 3 minutes.
5 " " " " " " 8 to 10 minutes.

Oxynaphthoic acid. Also derived from coal tar. It is the counterpart among the naphthaline derivatives of salicylic acid, which is found among the benzole derivatives, and it is said to be a more powerful germicide than salicylic acid.

Dissolves in 1 to 30,000 of water; soluble in ether; saturated watery solution is effective in exposures of forty minutes. Four per cent. in ether about the extent of solubility; four minutes.

*Carbolic acid.
1 to 20 destroys vitality in exposures of ¼ minute.
1 to 40 " " " " " ½ to 1 minute.
1 to 60 " " " " " 4 minutes.

Aseptol (orthophenosulphonic acid) readily soluble in water.

33⅓ per cent. solution destroys vitality in exposures of 30 seconds.
1 to 12 " " " " " 3 minutes.
1 to 100 " " " " " 4 hours.

Thallin (methyloxybenzol). Derived from phenol; 1 to 10 solution in water destroys vitality in exposures of three hours.

Terebene. Derived by the action of sulphuric acid on turpentine. Pure, it requires fifteen minutes to destroy the vitality of germs.

"Sanitas," a product obtained by the passage of oxygen through turpentine in the presence of water, is used largely by the profession in England, and in quite a large number of hospitals in this country. It is found on the market in the form of oils, a disinfecting fluid, and some other preparations. Although, according to Jewett (*Medical Register*, Philadelphia, 1888, iii., 152), it is a complex body, it probably owes its germicidal properties to the presence of the peroxide of hydrogen which it contains. It is non-poisonous and but slightly irritating to the tissues.

Oil No. 1, destroying vitality in exposures of 20 seconds.
" crude,[1] " " " " " 1½ minute.
Disinfecting fluid, " " " " " 4 "
" " fifty per cent., in " " 10 "

*Alcohol. "Koch's conclusions that absolute alcohol has little effect on dried germs is confirmed by Sattler and others; on moist germs, however, the facts are quite different."

Absolute alcohol destroys vitality in exposures of 4 to 12 seconds.
90 per cent. " " " " " 20 to 30 "
66 " " " " " " 10 to 15 minutes.

*Salicylic acid. Dissolves in water in the proportion of 1 to 600; ranks high in the list of antiseptics.

1 to 700 destroys vitality in exposures of 1 minute.
1 to 1,000 " " " " " 4 to 5 minutes.

*Salicylate of soda, in solution of 1 to 10, destroys vitality in exposures of eight to ten minutes.

[1] Not used in medicine. In coarse disinfection.

Salol. Not soluble in water, soluble in ether.

1 to 10 in ether, destroys vitality in exposures of 15 minutes.
1 to 20 " " " " " " " 35 "

*Chlorine water. Distilled water saturated with chlorine gas is placed by Sattler at the head of the list of germicidal remedies. It is certainly an excellent germicide, causing but little irritation of the tissues with which it comes in contact. Unless kept tightly corked, and in a cool, dark place, the solution rapidy loses its germicidal value by escape of the chlorine gas that it contains. Fresh preparations destroy the vitality of germs in exposures of one to one and half minute.

Chloride of lime, one of our best germicides, but not very stable—destroys colors, metals, etc.

1 to 100 destroys vitality in exposures of 4 to 8 seconds.
1 to 200 " " " " " 10 "
1 to 500 " " " " " 30 "
1 to 1,000 " " " " " 1 to 2 minutes.

Chlorinated soda (Labarraque's solution) corresponds very closely to the chloride of lime in regard to its stability and the actio.1 on colors, metals, etc.

The fresh solution destroys vitality in exposures of 4 seconds.
1 to 2 " " " " " " 8 "
1 to 10 " " " " " " ¾ minute.

*Hydrogen dioxide ($H_2O_2$). "Commences to decompose at a temperature of 60° F., giving off oxygen and being converted into water." Prepared under a pressure of two atmospheres and at a low temperature, the fresh preparation destroys the vitality of germs in exposures of one minute. When loosely corked, it loses its germicidal value quickly. "It should be kept on ice and tightly corked."

Bete naphthol disolved in ether.

1 to 10 destroys vitality in exposures of 30 seconds.
1 to 20 " " " " " 1 to 2 minutes.

Ichthyol (sulph. ichthyolate of sodium, or of ammonium, according to the alkali used) is soluble in water. It is said to be of great value in eczema, furunculosis, erysipelas, arthritic rheumatism, etc. Its remedial value is probably largely due to its germicidal properties. It destroys the vitality of the staphylococcus pyogenes and typhoid bacillus in exposures of three to four minutes.

*Sulphuric acid, 1 to 10, destroys vitality in exposures of three-fourths to one minute.

Listerine. Mentioned because of its rather extensive use by the profession as an antiseptic.

Undiluted destroys vitality in exposures of 1 minute.
1 to 2 " " " " " 8 minutes.

Chloride of iron.

1 to 10 destroys vitality in exposures of 3 minutes.
1 to 20 " " " " " 5 to 7 minutes.

Liquor of the chloride of iron.

1 to 20 destroys vitality in exposures of 3 minutes.
1 to 100 " " " " " 30 "

Tincture of the chloride of iron.

Undiluted destroys vitality in exposures of 10 seconds.
1 to 50 " " " " " 5 to 7 minutes.
1 to 100 " " " " " 15 minutes.

The acidity of the two last-mentioned preparations adds to their germicidal value.

Balsam of Peru requires an exposure of three minutes to destroy the vitality of the staphylococcus pyogenes. Its efficacy when used to dress suppurating surfaces is very probably due largely to its germicidal properties.

Iodoform and ether. Iodoform dissolved in ether, 1 to 10, destroys vitality in exposures of five to seven minutes.

*Boric acid. The staphylococcus pyogenes retained their vitality when mixed with a saturated solution of boric acid and allowed to remain ten days. Sternberg claims that in the proportion of 1 to 400 boric acid prevents the development of germs. It certainly does not destroy their vitality, therefore is useless as a germicide.

*Strong's water of ammonium. No effect in exposures of ten minutes.

*Potassic sulphate of alum. No effect in exposures of two hours.

Solutions of the substances mentioned below have no effect on the vitality of the staphylococcus pyogenes in exposures of twenty-four hours. Solutions in water unless otherwise stated.

*Arsenious acid, sparingly soluble; *Bicarb. of soda solution, 1 to 13; *Bromide of potash solution, 1 to 10; *Chloral hydrate, 1 to 50; *Castile soap, 1 to 50; *Common laundry soap, 1 to 50; *Camphor water; *Carbonate of ammonium, 1 to 5; *Chloroform; *Ether, sulphuric; Glycerine; *Bicarbonate of potassium, 1 to 20; *Chlorate of potassium, 1 to 16; *Iodide of potassium, 1 to 10; *Chloride of sodium, 1 to 3; *Bicarbonate of sodium, 1 to 16; Hyposulphite of sodium, 1 to 5; *Sulphate of iron, 1 to 5; *Sulphate of copper, 1 to 5; Tannic acid, 1 to 10; Tar water (Infus. picis liq.); *Acetate of zinc, 1 to 10; *Sulphate of zinc, 1 to 10; *Chlorate of zinc, 1 to 20.

*Oils.*—The oil of eucalyptus globulus destroys the vitality of germs in exposures of one to one and a half minute; *Oil of cade, five minutes; Oil of thyme, eight to ten minutes.

Exposures of twenty-four hours do not suffice to destroy the vitality of the staphylococcus pyogenes with the oils mentioned below:

*Oil of cloves, *oil of turpentine, oil of santal, crude petroleum, *thymol, pure and in watery solution; *benzole.

*Ointments.*—The following ointments produce no effect on germs, in a watery menstruum, although mixed with the ointments and left so exposed for thirty-six hours:

*Mercurial ointment (officinal), *ointment of the yellow oxide of mercury, one and a half per cent.; *ointment of the benzoate of mercury, one and a half per cent.; *ointment of iodoform, ten per cent.; *ointment of iodol, ten per cent.

This is in accord with the experiments made by Koch and others. It is possible that the effect produced on germs, on the skin and in the tissues, may be different. Germicidal remedies combined with oils and fats are probably less effective when combined with germs in a watery menstruum, because of the difficulty of inducing *immediate* contact.

*Powders.*—In nearly all cases an intimate mixture of the germs with the powders was made and cultivations taken from these mixtures.

*Calomel destroys vitality in exposures of three minutes; *resorcin, eight to twelve hours; *bete naphthol, eight to twelve hours. *Iodoform retards development after twelve hours' exposure. *Iodol and the following have no effect in exposures of thirty-six hours: *Chrysophanic acid, subiodide of bismuth, *subnitrate of bismuth, *boric acid.

*Thermal.*—*Boiling water destroys the vitality of mature germs on contact.

Leaving out of consideration remedies that are not germicidal in exposures of twelve hours, we have the following-named effective germicides, ranged in the order of their value:

Bichloride of mercury, chloride of lime (fresh), chlorinated soda (fresh), chlorine water (saturated), nitrate of silver, salicylic acid, creasote from birch-wood (Merck), alcohol (absolute), carbolic acid, "Sanitas" oil No. 1, "Sanitas" crude, potassium permanganate, bisulphate of mercury, "Sanitas" disinfecting fluid, creolin, trichlor. phenol (in ether), hydrogen dioxide, aseptol, listerine, oil eucalyptus globulus, iodoform and ether, balsam of Peru, oil of thyme, chloride of iron, tincture chloride of iron, liquor chloride of iron, iodide of silver, naphthalin in ether, oxynaphthoic acid, ichthyol, oil of cade, biniodide of mercury, oxycyanide of mercury, yellow oxide of mer-

cury, red oxide of mercury, bromide of mercury, resorcin, bete naphthol, potassium hydrate, thallin, terebene, iodoform.

It is thus seen that our list of effective germicidal remedies is relatively large, and is, I think, sufficiently complete.

43 West Eighteenth Street.

## CONCERNING SOME UNUSUAL ERUPTIONS.

By CHARLES W. ALLEN, M.D.,

formerly attending physician for skin diseases at the post-graduate university, northeastern and northwestern dispensaries.

In practice one is apt to encounter interesting and instructive cases, and to make observations on the results of treatment which, though perhaps worthy of record, are not of sufficient scientific importance to warrant consideration in separate articles.

In the following notes I will endeavor to give some impressions recently gathered from practice:

*Scarlatiniform Erythema.*—This is an interesting and not fully appreciated or understood condition, of which one now and then sees instances. It may occur under a variety of conditions, and be limited to a single attack or appear as a recurrent affection. The resemblance which the eruption bears to that of scarlatina is striking, and the subsequent desquamation makes it still more resemble the latter disease. Though in many cases this peculiar erythema is due to the ingestion of drugs, in other instances this cause cannot be assigned. It not unfrequently follows surgical operations, and may in some cases be due to septic poisoning or pyæmia. The following case has recently been under my care: Mr. G—— complained on March 9th of intense headache, fever, chilly sensations, and coryza, and the tongue was thickly coated. A drachm of antipyrin was given in four doses. The next day the headache had entirely disappeared and the patient felt well; but two days later a bright scarlet eruption appeared over the back of the neck, in the bends of the elbows, and to a limited degree upon the sides of the trunk. Temperature, 102° F. Headache severe. Antipyrin, gr. xv., was ordered to be given every four hours. On the following day the scarlatina-like eruption was more intense, and an erysipelas of the face first showed itself, beginning upon the nose and extending by the 15th to the whole face and ears, and by the 20th to the lateral surfaces of the scalp. The erysipelas ran through a regular course, creeping from one region to another, leaving crusts where the bullæ had been most noticeable upon the cheeks and about the eyes, and being followed by extensive falling off of the hair and beard.

The scarlet-like rash became confluent upon the back of the neck, sides of chest, across the lumbar region, and over the lower part of the abdomen and in the popliteal spaces. Upon the arms it was almost wholly confined to the flexor surfaces, and was but sparsely scattered over the legs, backs of feet, hands, and chest. It had nowhere an erysipelatous appearance, was not at all glazed, and no sign of vesiculation existed anywhere excepting upon the face.

Upon the chest, just in front of the axillæ, and upon the back and sides of the trunk there occurred a noticeable mottling or measle-like eruption of bluish macules, and just in front of the axillary fold there were purplish hemorrhagic spots, from which the color disappeared on pressure. These persisted after the erythema had disappeared, and in the subsequent desquamation, which was not completed before April 10th, these macules, which had taken on a faint brownish color resembling a fading macular syphilide, were the last to lose their epidermis. In some respects, especially in this subsequent measle-like eruption, the case resembled one of antipyrine eruption of the whole body which I saw two years ago.

Just how much the drug had to do with it, and what part the erysipelas played in the process, I am unable to say. That it was not scarlatina, though at first very closely resembling it, I am sure. Five children, none of whom had ever had scarlet fever were in the room much of the time, and some of them would surely have contracted it from what would have been a severe attack if the case had been one of scarlatina. Furthermore, the tongue and throat presented the appearances found in erysipelas, and not those of scarlet fever, and the rash persisted after the eighth day.

*Pityriasis Maculata et Circinata.*—This disease, to which Gibert gave the name "Pityriasis Rosé," has not been so frequently described in this country that a few words will be amiss. Possibly we may find here, as they have found in France, that instances multiply as the condition becomes better known and does not continue to be confounded with eczema, psoriasis, tricophytosis, and syphilis. The small, rosy, erythematous spots, covered with fine scales, increasing at the periphery while the centre clears up, just as in ringworm, forming irregular patches and circles, characterize this disease, which affects primarily the upper regions of the chest for the most part, but is capable of extending to the arms and thighs, and may, in fact, occur on any region of the trunk or extremities. The affection runs a cyclic course, and ends in recovery after a few weeks or months. It may recur, as instanced in one patient whom I have treated for the affection, no less than four times in as many years. The first attack was in 1884, when the trunk was covered with irregular patches and more or less complete circles. Sulphur baths produced an irritant effect and appeared to aggravate the condition. The second attack was in December, 1885; the third in January, 1887; and the fourth in January, 1889, which had disappeared by the first of February under applications of naphthol. None of the subsequent attacks were as severe as the first.

Mr. V——, twenty-one years of age, came under my observation on December 13, 1888. He had an acute eruption of circular itching spots covered with fine dry scales upon the upper portion of the chest, especially above and below the clavicle, while upon the back the lesions took the form of circles and segments of circles, with a smooth centre, which, however, also became scaly on scraping. Though resembling a seborrhœal eczema in a degree, the location, irregularity of form, dryness of the scale, etc., served to distinguish it from this affection. By January 1st the spots had all disappeared, under sulphur baths and applications of an ointment containing sulphur, zinc oxide, and carbolic acid. Up to the present date there has been no return.

*Molluscum Contagiosum.*—Many authorities persist in teaching that this affection is not contagious. I have recently had several cases of this soft, wart-like growth, occurring upon the face and elsewhere in children, which strengthen my opinion, as expressed in an article in the *Cutaneous Journal*, of August, 1886, that it is undoubtedly of a contagious nature. In December of last year I was asked to see a boy, four years of age, who had "a large sore under his eye and a number of warts upon the face." The history given was that three months previously the mother had been a nurse in a children's asylum in this city, where the child lived with her. One of the inmates, a little girl, had "warts" upon her face, and the mother cautioned her boy not to play with this child, as he "might catch them." Despite this warning, the young people were frequently found together, as is often the case in true love, and one day they were discovered kissing. After this the mother always said to her son: "Now you will get the warts." And he did. Before they left the institution, two months previous to my seeing the patient, the mollusca had begun to appear. The first one noticed was that under the eye, which had now become much inflamed and ulcerated, and measured at least a centimetre in its long diameter. Beneath this, and extending toward the nose, were four smaller tumors; two were on the lower lid, one upon the upper, one at the outer canthus of the

eye, one upon the ear, and one upon the chin. All were upon the same side of the face as the original lesion, and had appeared at varying intervals, but mostly since the large mollusc began to suppurate. The lesion which had last appeared was upon the opposite brow. The growths were all removed at one sitting by scraping out with Vidal's sharp scoop. A second operation became necessary upon the large tumor beneath the eye, which began to grow again, but after the stick of nitrate of silver was applied to the bleeding base it was permanently cured. No scars resulted, and no reappearance of the affection took place.

I visited the institution to find and examine the girl in question. She had left, but I was permitted to visit the wards with the house-physician, and discovered six patients with small molluscum tumors upon the face. The house-physician told me that when he had entered the institution only one child had shown these growths, that the others had since developed, and that he had not looked upon them as contagious, and had instituted no treatment. Another instance pointing to contagion was seen on April 22d of this year.

M. J——, aged ten years, presented herself with sixteen mollusca upon the face. One inflamed and suppurating nodule upon the chin, the size of a white bean, was recognized as the original lesion, and the story told was that, three months before, the patient sat in school next to a girl whose face was covered with similar "warts." The girl had been dismissed from school on this account, and I could not trace her. Shortly after this the first mollusc appeared upon our patient's chin, and the rest are of recent growth. One by the side of the nose had become horny at the summit, elongated, narrow, and presented much the appearance of the filiform wart occasionally seen upon the eyelids. A little girl, of about the same age, who accompanied this patient, and who lived in the same house with her, had, in fact, one of those filiform warts growing from the under eyelid, which was half a centimetre long, as big round as a pin, and very horny at the free extremity. The base looked much like the molluscum when cut out. It is possible that the filiform wart occasionally originates in a small molluscum tumor. When excised and examined the papillæ are found not to be involved as in other forms of warty growth, but to be made up of epithelial and connective-tissue elements, resembling more the fibrous mollusc. Furthermore, they are almost exclusively found upon the eyelids, breasts, and neck, regions often the seat of molluscum tumors.

There is one point I wish to make in relation to the etiology of molluscum contagiosum. If it depended upon any other cause than contagion, as some authors maintain, why should cases cease to appear in an institution after all the lesions had once been removed from the skin of the various children affected?

I think the fact that new lesions continue to appear upon a child's face so long as the older lesions are allowed to remain, especially if they be suppurating or inflamed, and that the child continues wholly free from any newly developed growths from the moment these lesions are destroyed, goes far toward proving the disease to be autoinoculable as well as transmissible to others.

*Inoculation of Molluscum.*—Within the past month I have removed a molluscum contagiosum growth from the side of the fourth finger of a physician of this city, who, as ophthalmic surgeon to one of our large orphan asylums, where molluscum contagiosum is epidemic, has of late removed many such growths from the faces of his little patients, fifty or more of whom have had the disease. The doctor had made the diagnosis in his own case, believing he had contracted it in this way, and came to me knowing it to be a question in which I was interested. What can this be but a case of inoculation? Sometimes the mollusc tumor attains such a size and takes on such an unusual appearance as to make the diagnosis obscure. Two weeks ago I removed such a growth from a little girl's cheek, which was as large as a cherry, deeply embedded in the skin, covered with thin pinkish skin, and having a minute central opening through which sebaceous-like material could be pressed. When scooped out, a hole was left in the cheek which would admit the end of the thumb.

I have notes of several instances where one only of several brothers and sisters has shown the growths, the history being that this particular child had a playmate or intimate similarly affected, with whom the other children did not associate to the same extent or not at all.

*Dermatitis from Oil.*—I have had a number of cases of follicular dermatitis of the hands, arms, and thighs, in machinists and those whose work brings them into contact with paraffine, fish, and other oils. The lesions are papular, pustular, and furuncular for the most part (in one case the furuncular element predominated), and occur upon the exposed parts, such as the hands, arms, and also the region of the knees and thighs of those who work in machine-shops, wire and silk factories, etc.

Very much the same variety of dermatitis is occasionally produced by benzole, chrysarobin, and similar drugs.

The papular and pustular lesions on the arms and legs (mostly the inner surfaces of both limbs) might be called "oil acne." It develops only on the parts which come in contact with the oil, or with the clothing which has become saturated by it. In one case, in which the lesions were principally boil-like, occurring in an employee of a wire factory where fish-oil was used, peculiar concentric annular rings of erythema appeared about the furuncles on the hands and arms.

Since the summits are often dark-colored from the accumulated oil and dirt, the lesions are spoken of by the men in such factories as "black boils."

In some cases the inner surface of the forearms and the region about the knees become rough, harsh, and dry.

Recovery is rapid after the cause has been removed. When the occupation cannot be changed I order repeated washings with green soap, followed by bland ointments and protective dressings. The oil-soaked clothing must be discarded, and subsequent care and cleanliness exercised.

*Purpura.*—Among the cases of purpura of which I have notes, I find several interesting in the matter of differential diagnosis. On May 9, 1887, I saw a young girl whose limbs and portions of the trunk were literally covered with purple spots, which close inspection showed to be simply the result of flea-bites (purpura pulicosa).

The lesion usually produced by the bite of the *Pulex irritans* is an erythematous spot with a central point, but so closely does it at times resemble a true purpura that the error has been made of so regarding it, and an epidemic of "purpura" has been reported which turned out to be one of flea-bites only.

On January 11th I saw a four-year-old boy, S. S——, whose whole body was covered with purple dots the size of a pin's head and who had a "black eye." Ecchymosis of the eyelids was accomplished by a hemorrhage into the sclerotic, all due to the violence of coughing in pertussis. These hemorrhagic lesions disappeared in due time as the cough grew better, a few new purpuric spots appearing now and then as the case progressed. On April 23d the child began coughing violently again, after an apparent cure had been effected, and the purpura again made its appearance, and the tissues about the eye showed the same ecchymosis. In about three weeks' time the child was well again, the spots having in the meanwhile disappeared.

*Favus.*—Favus is much more prevalent in New York than is generally supposed. It is confined for the most part, as yet, to those who have brought it with them from the old world. Russian, Polish, Hungarian, and other boys, who have the disease in its most active and dangerous form, are to be found in our down-town public schools playing with other children out of school, exchanging hats with comrades, and exercising no care

in the use of combs and brushes, hence it is fair to presume the time will soon come when more American-born children will become affected. It is sometimes surprising to note how long the germs will remain active after the disease has appeared to be cured. I have repeatedly seen adults with a great portion of the scalp permanently bald, as a result of the ravages of favus contracted in childhood, who have shown evidences of renewed activity of the favus after having for a number of years considered themselves entirely well. It is very difficult to induce patients with favus to stay under treatment long enough to effect a permanent cure. As soon as the scalp appears well they are satisfied and neglect treatment, and if in an institution insist upon leaving.

The parents, too, have such a high appreciation of the advantages offered by our public-school system that they will not keep their children at home even when most strongly urged to do so. It is self-evident that the schools should exclude children with such a contagious disease and one so difficult to cure.

The following history illustrates how readily at times the disease may be transmitted to those in close contact with a favus patient, as from a mother to her child, a patient to a nurse, etc.:

M. S—— was transferred from Bellevue Emergency Hospital to Charity Hospital, with her child, on November 1, 1886. She gave a history of favus of fifteen years' standing. On admission the disease involved the entire scalp, and favus cups were well developed. Her baby first showed signs of the disease about November 14th; three spots appearing on the head, and one on the arm. About one week later the nurse, Miss W——, and a ward helper were attacked, three spots appearing on the forearm of the nurse, and one on the arm of the helper (who is now said to have his scalp involved). A few days later spots developed on the arm and head of another baby, which were suspected by the house physician of being the same affection. On the wrist of Miss W——, the nurse, pustules appeared three or four days after the onset, and these were followed by well-developed favus cups. She has been treated by pure carbolic acid, collodion with hydrarg. bichlor. (gr. iij. to ℥ j.), and subsequently with ung. hydrarg. ammoniat. When I first visited her, on December 16th, the lesions were still present upon the arm of the nurse, but they soon disappeared after friction with the tincture of green soap, then applying ammoniated mercury, ʒ j. to lanolin ℥ j., and, after a few days, painting the part with four grains of bichloride in an ounce of collodion. To effect a cure in favus of the scalp, the hairs must be epilated from the whole diseased area while parasiticides are being employed.

*Leprosy.*—The case of leprosy which I presented at the County Medical Society in February, 1888, to show the beneficial effects of surgical treatment, has continued to improve ever since; the face being to-day quite free from leprous nodules or tubercles. The ulnar nerve has decreased to about one-half the size it then had, and the infiltrations upon the thighs and trunk have in a great measure disappeared. The anæsthesia of the hands has improved to such a degree that the slightest stick or pinch is now felt, and the patient can use his hands much better than formerly. This is especially noticeable in opening doors, buttoning his clothes, etc.

These favorable results have been brought about by the almost constant employment of large doses of chaulmoogra oil. Beginning with ten-drop doses in capsule three times daily, the patient has gradually increased the dose until at times he has taken as many as ten capsules, or one hundred drops at a dose, three times a day, making three hundred drops as a daily dose. This is a larger dose than I have known any patient to stand. In Paris last year I saw a leper who had taken as high as two hundred and ten drops daily for a short time.

Besides chaulmoogra oil internally, our patient has used chrysarobin and pyrogallol externally in ten per cent. ointment at times, but not with sufficient persistence to materially affect the general condition or to have much share in the improvement.

*Dermatitis and Eczema from New Flannel.*—Last winter I was asked to see seven babies in the Infant Ward of Charity Hospital, who had simultaneously developed an eruption of the skin. They were all found to be similarly affected with a maculo-papular eruption over the face, neck, arms, and hands, while about the buttocks and folds of the groin either intertrigo, dermatitis, or eczema, and sometimes all three varieties of lesion, were present. Examination and inquiry elicited the fact that all of these children had been wearing undergarments and skirts made of new red flannel which had not been washed. I took pieces of this flannel and tested them for arsenic and coraline, but finding neither of these poisonous substances present, concluded that the eruption was induced by the irritant nature of the new flannel alone upon the delicate skin of the infants, having frequently seen this effect of new flannel upon the coarser skin of adults, where it is capable by long contact of exciting an eczema.

*Verruca on Vermilion Border of Lips.*—Since this condition is one rarely observed, and as Dr. Elliot presented a case at the last meeting of the Dermatological Society, being the only one he had ever seen, I am led to report three cases which have come under my observation during the past year.

One young girl, eleven years of age, was seen on April 13th. She had sixty warts on one hand, thirty-three on the other, twenty-nine small ones on the face, and seven upon the vermilion border of the upper lip, the largest one being situated upon the mucous membrane of the inner surface of the lip, quite within the mouth.

The parent wart was upon the end of the index-finger of the left hand, and had existed for two years. At the present time it is fissured and moist. The warts have existed upon the face and lips for about a year.

On December 2d of last year I saw a young boy who had upon the mucous border of the lip three small warts arranged like a chain of beads. He had had a large "seed"-wart upon the hand for about two years.

The third case was in the person of a little girl, who came to the Northwestern Dispensary on November 5, 1888. She had twenty-three warts upon the hands, two upon the arms, and one upon the vermilion border of the upper lip. They were all removed with the sharp spoon. It will be noted in all of these cases that warts of long standing were present upon the hands, and in each case there was a large wart (usually the first one noticed by the patient), which had reached the condition known among children as a "seedwart." In my experience, when this parent wart, as we may call it, is once thoroughly removed, other new warts cease to appear, especially when all warts present upon the body are radically cured at the same time. This is also true of molluscum contagiosum, as already stated, and appears to me to give much weight to the popular opinion that warts are contagious.

I have already reported, and, so far as I am aware, have been the first to call attention to it, that molluscum contagiosum may occur upon the vermilion border of the lips. A wood-cut accompanying my article in the *Cutaneous and Venereal Journal*, August, 1886, shows the location of several molluscs in this region.

---

VISCUM FLAVESCENS, AN OXYTOXIC.—Dr. Daniel Gray, before the Ogeechie Medical Association of Alabama, demonstrated that a tincture prepared from the leaves of *viscum flavescens* (Pursh.) is an oxytoxic of great value. A number of cases in which this effect was obtained were cited, in two of which, at least, it exhibited all the good properties of ergot. His first attention was called to this use of the mistletoe, by the fact that it is employed by the stock-breeders to secure the expulsion of retained secundines in cows. He further declared that the activity of the growth appeared to depend upon the tree to which it was parasitic, the best medicinal mistletoe being that found on the persimmon.—*Medical Age.*

## ON THE RELATION BETWEEN THE DISEASES OF THE TEETH AND EARS.[1]

By ROBERT BARCLAY, A.M., M.D.,

FORMERLY ASSISTANT AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY, NEW YORK; CONSULTING AURAL SURGEON TO THE CITY HOSPITAL AND ST. MARY'S HOSPITAL, ST. LOUIS, MO.

MR. PRESIDENT AND GENTLEMEN: If, in your practice, you recognize the presence and influence of reflected oral irritation as a leading factor in the predisposition, production, and continuance of aural symptoms and diseases of the ear, and forthwith get rid of it, if possible, you will find success more promptly attend your therapeutic efforts, and a recurrence of the aural phenomena less frequent. Among the principal conditions giving rise to oral irritation may be found cutting, crowding, shedding, and caries of the teeth, gingivitis, hyperostosis, pyorrhœa alveolaris, periostitis (pericementitis), tartar, hypertrophy of the gums, catarrhal inflammation of the buccal mucous membrane, vulcanized red rubber and ill-fitting plates and dentures, numerous amalgam fillings, and unskilful dentistry.

The following illustrative cases are worthy of your consideration:

CASE I.—A German clergyman, aged thirty-seven years, consulted me for slight deafness, tinnitus, and occasional pain of the right ear, which is worse on "taking cold." Treatment availed little until after the removal of a supernumerary right upper wisdom tooth which was hidden beneath the gum, when he soon recovered.

CASE II.—A clerk, eighteen years of age, applied for relief of intermittent otorrhœa and attendant symptoms of left ear, of fifteen years' duration. Cure was effected in less than four weeks; and no recurrence took place until nearly nine months afterward, when the lower wisdom tooth of corresponding side was found in eruption. The discharge persisted until this was fully cut, when it ceased.

CASE III.—A clerk, nineteen years of age, applied for treatment of otorrhœa and attendant symptoms of left ear, of about eleven years' duration. Within five weeks he was cured of this, and had no recurrence until one year afterward, when former symptoms and otorrhœa returned. The lower wisdom tooth of this side was cutting, and otorrhœa would not cease until this was fully cut.

CASE IV.—An Englishman, thirty-four years of age, a conductor, consulted me for otorrhœa and attendant symptoms of left ear, of about twenty months' duration. There were many carious spots in the teeth and the left lower second molar tooth was very carious. After three months' treatment, the otorrhœa had almost ceased, when he placed himself under a dentist's care. The dental operations aggravated the otitis and the discharge grew worse. Treatment of the ear was steadily persisted in until after the teeth had been put in good order. Improvement in the aural trouble began immediately after the dental treatment was suspended, and the patient was dismissed shortly afterward.

CASE V.—A young lady, about eighteen years of age, consulted me for deafness, slight discomfort, and tinnitus of the right ear, which she had first discovered on awakening in the morning ten days before. There was cerumen in both ears, impacted in the right. Both upper wisdom teeth were carious.

CASE VI.—A lady, twenty-five years of age, a teacher, came for treatment of deafness of left ear, which had begun about one year before, but which had grown much worse of late. A sensation of sound sometimes persisted after the sound had ceased. She had confused hearing when several people were speaking simultaneously. Deafness was very marked. The drum-head appeared paler than normal. For some time she had been cutting both left wisdom teeth. When the right lower one was cut later, the right ear began to be affected, but treatment checked further aural trouble.

CASE VII.—A drug clerk, eighteen years of age, consulted me for intermittent left earache of several months' duration. This was worse at night. He had chronic nasopharyngitis. There were no particular physical signs nor subjective symptoms of an otitis to account for the intense earache. The left upper second molar and both left lower bicuspid teeth were carious. A slight Politzer inflation and removal of the decayed teeth gave permanent relief from earache within a few hours.

CASE VIII.—A German, fifty-six years of age, a yard-laborer, came to me for relief from profound deafness, tinnitus, autophonous voice, and slight itching pain in his ears, of five months' standing. Twice before this, at several years intervals, he had had similar trouble, developed suddenly after wetting his head and exposure to cold. Impacted cerumen was found in both ears. Of his teeth, seven from the upper, and eight from the lower jaw, are missing. There are carious: Both right upper incisor, the canine and both bicuspid; both left upper incisor, the canine, and third molar; the right lower central incisor, canine, and first bicuspid; and both left lower incisor, the canine, second bicuspid, first and second molar teeth.

CASE IX.—An Englishman, twenty-two years of age, a blacksmith, came for relief of slight deafness, autophonous voice, tinnitus aurium, vertigo, and weakness of several weeks' duration, on account of which he had been compelled to quit work. Cerumen was found in both ears. He was cutting his wisdom teeth.

CASE X.—A Frenchman, forty-six years of age, a mechanic, came to me for relief from slight pain, tinnitus, deafness, and autophonous voice, of three months' duration. He was very deaf; and during mastication could hear no ectogenetic noise. Cerumen was found in both ears. Of his teeth, three are missing from each jaw. There are carious (mere roots and shells only remaining of these): The right upper second bicuspid, first and third molar; the left upper first and third molar; the right lower second bicuspid; and the left first and third molar teeth.

CASE XI.—A carpenter, fifty years of age, born in Ireland, came to me for relief from severe deafness, autophonous voice, and varying tinnitus aurium, with violent ear-cough, of one month's duration. Mastication sometimes caused odontalgia. There was a small nasal polypus. Cerumen was found in both ears. Of his teeth, there were carious: The right upper second bicuspid, first and second molar; both left upper bicuspid, and three molar teeth; and the right lower first and second molar teeth.

CASE XII.—A flagman, fifty-seven years of age, born in Ireland, sought relief from violent itching in his right ear, with autophonous voice, tinnitus, and deafness of both ears. Both drum-heads were somewhat retracted. Both upper wisdom teeth decayed to mere shells.

CASE XIII.—An Englishman, forty-two years of age, a car-builder, came to me for relief of pains which radiated from the ears in various directions, sometimes settling behind the eyeballs, as it were. This, and deafness, with autophonous voice, and tinnitus of both ears, had lasted some years. There were ingrowing hairs and cerumen in both external auditory canals. Of his teeth, five in the upper, and one in the lower jaw, were missing. There were carious: The right lower first molar, left upper second molar, and left lower second bicuspid teeth. The crowns were worn off all the upper incisor and left upper canine teeth; the roots of the right upper second molar and left upper first molar teeth are exposed; the right lower canine tooth is crowded out of the arch; and the lower teeth are covered with tartar.

CASE XIV.—A woman, thirty-eight years of age, employed in housework, consulted me for a "dumb-aching," with "roaring and ticking," and slight deafness of left ear, and with pains shooting from the angle of the lower jaw to the vertex. This had persisted for four weeks, and

[1] Read before the Medico-Chirurgical Society of St. Louis, Mo., June 25, 1889.

was aggravated by scrubbing a floor, or blowing the nose. There was slight dulness of the drum-head and a few dirty spots thereon, with slight myringeal congestion. The left upper second molar, and central and lateral incisor teeth are very carious. There are cavities in the left lower back teeth, and some on the right side also.

CASE XV.—A clerk, twenty-four years of age, applied for relief of symptoms of catarrhal otitis media, aggravated of late, worse on the right side. The drum-heads showed peculiar but characteristic trophic changes. Both lower wisdom teeth, for two years, have been coming through the gum, and causing discomfort. The right one is coming in directly forward, against the second molar tooth; the left, almost backward, along and in the jaw and gum, and cannot get out. The right upper wisdom tooth is through, the left one not yet through cutting.

CASE XVI.—A school-girl, twelve years of age, came to me with intermittent earache of both ears, of two months' duration. She said she had had a slight "discharge" from the left ear two months before, at which time she had had much odontalgia also. The drum-heads show no characteristic changes. She has five very carious teeth.

CASE XVII.—A clerk, twenty-four years of age, applied for relief from tinnitus and slight deafness of left ear, of one week's duration. Cerumen filled the canal of the left ear. There was one carious upper tooth on the left side.

CASE XVIII.—A middle-aged woman, born in Ireland, employed in housework, applied for relief from tinnitus of the right ear, worse at night, of two months' duration. She had occasional odontalgia. No marked changes of the drum-head were found. Her right upper teeth were decayed to mere shells.

CASE XIX.—A boy, aged eighteen months, was placed under my care for abscess of the right ear, which had been developing for some days, and had ruptured the preceding night. He had had an attack of tonsillitis one week before. The right lateral incisor tooth had been cut about that time. The left upper canine tooth was cut five days, the right upper and both lower anterior molar teeth eight days, and the right upper canine tooth about sixteen days, after being first seen by me. The otitis persisted until after these teeth were fully cut, when it readily passed away under treatment.

CASE XX.—A clerk, thirty-two years of age, came to me for relief of deafness and autophonous voice, of six days' duration. There was tinnitus of the right ear, and numbness about the right auricle. He had had a similar attack three years before. Cerumen was found in both ears. He was wearing, when seen, a vulcanized red-rubber dental plate carrying all the upper teeth, except the molars, which remain, covered with tartar. The six lower molars are missing, and the right upper first molar tooth is decayed to a mere shell.

In the *Archives of Otology*, New York, March, 1885, is an article—whose title I have borrowed for my own—written by Dr. Bruns, of New Orleans, La., containing a report of an examination of fifty cases taken from the wards of Charity Hospital "at random." Of these there were twenty-three whose "ears" were not "normal," of whom nineteen had "hearing" that was not "good;" and although the writer actually states that there were nineteen cases in whom the "hearing" was more defective on "the side on which the teeth were worse," yet, nevertheless, he draws the conclusion "that those cases are exceptional in which dental irritation gives rise to aural affections."

Dr. Samuel Sexton, of New York, in THE MEDICAL RECORD, June 1, 1889,[1] discussing "dentition, caries of the teeth, and some of the neuroses resulting therefrom," says that although the special-sense organs, the ear, nose, and eye, connected with the teeth and with each other through a complex nervous network, while in health "maintain an independent and separate existence, so to speak, their intimate sympathetic relationship scarcely manifesting itself perceptibly," yet, "under certain conditions of the system, however, these organs become strikingly susceptible to disturbing influences, and so far as his own experience goes, from no cause more frequently than from dental irritation." The same writer, in his Prize Essay, "On the Affections of the Ear Arising from Diseases of the Teeth," *American Journal of the Medical Sciences*, January, 1880, states that "on reviewing the records of some 1,500 cases, he finds that the teeth are more frequently the seat of disease than was at first suspected, for of these 1,500 aural cases, perhaps one-third owe their origin or continuance, in a greater or less degree, to diseases of the teeth." And again, "that all of the morbid conditions of the mouth which have been herein described may exist without serious or recognizable aural affection being developed, cannot be denied, but progressive disease of the ears, often without the occurrence of pain, is, in his experience, more common when these oral affections are present than when the mouth and throat are in a healthy state." Those who desire an instructive analysis of this subject will do well to consult those two essays.

Presuming that the gentlemen to whom these remarks are addressed are of course familiar with the anatomy of the nervous system and its connections between the mouth and ear, I shall therefore spare you a detailed description thereof, which may be found in any standard treatise on anatomy.

Oral irritation reflected to the ear produces, first, a change in the calibre of the blood-vessels, through vasomotor influence; this induces hyperæmia, pruritus, abnormal glandular activity, and congestion of the integument of the canal, and also of the mucous membrane of the tympanum. Organic changes result, and at the same time there is established a predisposition to exacerbations of the chronic process, and acute otitis may supervene.

Success by treatment based on local aural symptoms, and operative on local aural conditions only, is delayed and often impossible.

In cases, therefore, of obstructing accumulations, seborrhœa, eczema, zoster, diffuse and circumscribed inflammations of the canal, inflammations of the tympanum, earache—I may say in all cases having aural symptoms or disease, the oral cavity, as well as the nares and other parts of the upper respiratory tract, should be intelligently examined for irritation or disease, and if either be found there, it should at once be removed if possible. Should your acquaintance with oral pathology be so limited as to leave you in doubt as to the presence of oral irritation or disease, you will do well to seek counsel in diagnosis from a skilful dental surgeon.

## A SUMMER HEALTH-RESORT.

BY WILLIAM H. DAKEMAN, M.D.,
LOS ANGELES, CAL.

PHYSICIANS in search of climatic aid have been led to send their patients to the various summer places of note, such as the Catskill and Adirondack Mountains of New York; the White Mountains of New Hampshire; Berkshire, Mass.; Atlantic City and Long Branch, N. J.; Aiken, S. C.; Asheville, N. C.; Denver, Col.; and numerous other places at home, as well as the many renowned places abroad.

After careful study of this climate, I will attempt to show that we can add to the list a health-resort of superior advantages, the Pacific slope of Southern California, and particularly as a summer resort. A visit to this sunny land of a section of country lying along the Pacific coast, situate between latitude thirty-two and thirty-five degrees north, and between longitude one hundred and seventeen and one hundred and twenty degrees west, and comprising a portion of each of the four counties of San Diego, Los Angeles, Ventura, and Santa

Barbara, very favorably impresses the writer of the superior natural sanitary advantages offered, as being an almost perfect health-resort.

Much has been said and written, in reference to this section of country, as being a very favorable winter resort. But as a summer resort it is far superior. Both seasons, however, have their own peculiar advantages, and as a winter resort it has no equal. And Southern California is rightly termed "the sunny land," "the land of blue sky," "the paradise of the world."

In speaking of this, I have reference to that slope of land along the coast, from the city of San Diego to Santa Barbara, extending eastward for fifty miles from the coast to what is known as the Sierra Madre Mountains, including the fertile valleys and undulating foothills and mountain spurs, until an elevation of 6,000 feet is reached; and in which is contained the prosperous cities of Los Angeles, San Diego, Pasadena, Santa Barbara, Santa Ana, etc., and the seaside resorts of Santa Monica, Long Beach, Coronada, and Catalina Island, at which places bathing in the surf of the Pacific gives new charm and zest to our wearied existence.

Let us carefully make note of the following tables, as compiled from the United States Signal Service Reports of the Los Angeles station.

*Table showing Temperature (Fahrenheit), Humidity (per cent.), and State of Weather for the Colder Six Months.*

| 1888–1889. | Mean temperature. | Highest temperature. | Average mean temp. for ten years, from 1878 to 1888. | Mean relative humidity. | Clear days. | Fair days. | Cloudy days. | Foggy days. | Rainy days. |
|---|---|---|---|---|---|---|---|---|---|
| November | 57.2 | 83.8 | 58.1 | 74.1 | 15 | 8 | 7 | none. | 7 |
| December | 55.2 | 78.8 | 55.6 | 71.0 | 18 | 6 | 7 | " | 6 |
| January | 51.2 | 71.0 | 52.5 | 80.0 | 19 | 6 | 6 | " | 4 |
| February | 54.0 | 84.0 | 54.4 | 83.0 | 18 | 8 | 2 | " | 2 |
| March | 55.0 | 81.0 | 56.0 | 77.0 | 9 | 18 | 4 | " | 7 |
| April | 59.0 | 93.0 | 58.6 | 75.0 | 12 | 13 | 5 | " | 4 |
| Total | .... | .... | ..... | .... | 91 | 59 | 31 | .... | 30 |

*Table showing Temperature (Fahrenheit), Humidity (per cent.), and State of Weather for the Warmer Six Months.*

| 1888. | Mean temperature. | Highest temperature. | Average mean temp. for ten years, from 1878 to 1888. | Mean relative humidity. | Clear days. | Fair days. | Cloudy days. | Foggy days. | Rainy days. |
|---|---|---|---|---|---|---|---|---|---|
| May | 60.8 | 83.0 | 62.0 | 79.2 | 5 | 18 | 8 | none. | 1 |
| June | 67.5 | 94.0 | 65.3 | 74.1 | 17 | 12 | 1 | " | 0 |
| July | 67.9 | 95.0 | 68.1 | 75.6 | 18 | 13 | 0 | " | 1 |
| August | 7.6 | 97.0 | 69.8 | 79.4 | 23 | 8 | 0 | " | 1 |
| September | 68.4 | 98.2 | 67.6 | 77.7 | 21 | 7 | 2 | " | 0 |
| October | 61.9 | 98.0 | 62.5 | 82.3 | 16 | 10 | 5 | " | 3 |
| Total | .... | .... | ..... | .... | 100 | 68 | 16 | .... | 6 |

From the above tables we learn that the temperature for the warmer six months is a very few degrees higher than for the colder six months; that during the heated part of the day the mercury runs very little higher during the summer than during the winter; that the mean relative humidity is comparatively lower in summer than in winter; and we have more clear and fair days, and less cloudy days, and no rainy days in summer, giving us every day to be out of doors.

From the above tables we learn that during the warmer six months we had, out of the 184 days, 100 clear days, 68 fair days, or 168 sunshine days, and only 16 cloudy days. Of the 16 cloudy days, only on six different days did rain fall; three light showers occurred in daytime, and three light showers at night. During these six warmer months we find that the highest temperature was only 98° F., and from United States Signal Service Reports I find that it reached this point but twice, once in the month of September, and once in the month of October. And on but very few days did the temperature run up in the nineties. Generally the temperature, during the hottest part of the day, rarely reaches 95° F., and this always occurs between the hours of 10 A.M. and 2 P.M., after which there is a cool breeze blowing from the ocean. The heat, therefore, is at no time oppressive, but the weather is always comfortable, always cool in the shade; and as night approaches it grows from ten to twenty degrees cooler, making it very comfortable, and necessary at all times of the year to sleep under blankets. As the nights are always cool, one gets good, restful sleep, from which he awakes refreshed. It is generally remarked that a person requires more sleep in this climate than in a colder one—at least he is inclined to sleep more, and the consumptive rests in peace. It is to be noticed that we have no foggy days. But at certain times of the year, as night approaches, a fog blows in from the ocean, and sometimes in the morning we have a high fog, having the appearance of being cloudy. The relative humidity falls as the temperature rises, thus relieving us of that depressing feeling during the heated term. Take any given day, the temperature at 7 A.M. being 70° F., the relative humidity is about eighty-five per cent. From 10 A.M. to 1 P.M., the hottest part of the day, when the temperature may be 85° or 90° F., the relative humidity will be as low as fifty-five or sixty per cent.

From this we learn why the heat is never oppressive, and why sunstrokes never occur, and why one does not sweat away in perspiration, and seek the ice-cooler for comfort.

From the above table it will be seen that there are only four of the six warmer months where the average temperature reaches only 67° F. And we also learn that the mean temperature for the six warmer months, for the past ten years, has been at the average standard of only 67° F. The months of May and October are of about the same temperature, or several degrees cooler, averaging about 62° F. for the past ten years.

Here, in the six warmer months, we find comfort and peace from oppressive heat in a balmy climate. The clearness and purity of the atmosphere is remarkably refreshing and invigorating. There are no windy, nor wet, nor damp, nor foggy days, which gives us every day to be out in the open air, inhaling a pure aseptic atmosphere. Dr. Bodington, of Warwickshire, forty years ago, said: "To live in, and breathe freely, the open air, without being deterred by wind or weather, is one important and essential remedy in arresting the progress of phthisis."

Regarding the attractiveness of the scenery, those who have travelled much and visited this section of country are at once captivated with its grandeur and beauty, and generally concur in the opinion that there is no place so charming. It abounds in majestic mountain heights and cliffs, and romantic cañons and ravines, and fertile valleys of exquisite beauty, and rippling streams finding their way from the mountains to the great Pacific. Los Angeles, from its central position, can boast of many attractive drives over good roads to local places of interest, over rounding bluffs and beautiful valleys to points commanding views of billowy hills and distant amphitheatre of mountains, of most beautiful scenery, and a charming foothill drive to the ocean.

Los Angeles is a beautiful, thriving city, of about eighty thousand inhabitants. The principal streets are paved with asphalt or bituminous rock, and are kept clean by being swept every night. An outfall sewer to the ocean is soon to be constructed.

The resident portion of the city contains some of the most beautiful homes in America. They are surrounded by large green lawns, laid out with exquisite taste and beauty, and contain a variety of evergreen trees and palms, and semitropical plants and flowers of all descriptions. There is a beautiful park in the heart of the city, and several other parks are being laid out and decorated in an elaborate manner.

The city contains numerous finely constructed private hotels for the accommodation of the tourist and invalid, built in the resident portion of the city, away from the noise of the business portion of the city.

Seventeen miles westward from Los Angeles is the sea-

side resort, Santa Monica, where surf-bathing in the warm coast stream is most enjoyable, and can be indulged in every month in the year. Twenty miles southward is the seaside resort, Long Beach, and five miles from this, westward, is the port of San Pedro, where a steamer awaits the tourist for an ocean voyage of thirty miles, to Catalina Island, which place is a rapidly growing, popular summer resort. Good hotels with good accommodation will be found at each of these places, open to tourists during the summer months.

About one hundred miles southward from Los Angeles is Coronada Beach, with its renowned Hotel del Coronada of 750 rooms, beautifully situated, with grounds laid out with exquisite taste and beauty, and wide, magnificent views of mountain, ocean, and bay scenery, and whose surf-bathing is most pleasant and enjoyable, and where the sunny days pass away almost like a dream.

Regarding the healthfulness of this section of Southern California, statistics prove it to be the most healthful spot in America. From the Board of Health reports of the prevailing diseases, we learn that cholera infantum is an almost unknown disease among the little ones, which in our eastern cities carries away thousands upon thousands during the summer months. Diarrhœa and dysentery, which also swell the death-list up in the tens of thousands, are indeed of very rare occurrence, and the fear of the death of the babe, from these diseases, by those mothers who have lived East, is a thing of the past with them.

As there is no stagnant water, nor damp soil for the decomposition of vegetable matter for the development of malaria, intermittent and remittent fevers are equally as rare.

The purity of the water, which is derived from the mountains, which is free from contamination of sewerage and decomposed animal or vegetable matter, gives us almost perfect immunity from the more common zymotic diseases. When, however, such diseases do occur they usually run a mild course.

The even state of the temperature, with no days of oppressive heat; the purity of the atmosphere, with a low relative humidity; and every day to be out of doors, makes this section of country a most admirable one for consumptives. A patient with phthisis should come here in due time and remain at least two or three years, when in all probability, with due care, the progress of the disease will be arrested. Many such persons I see daily. The same may be said of those who are afflicted with diseases of the kidneys.

Having a climate here which is conducive to sleep, and which acts as a sedative to the nervous system to the many who are afflicted with nervous trouble, the result of overwork, or from other causes, for them no better place can be found on the face of the globe.

A case of pneumonia, which recently occurred in my practice, I here desire to report, as it will give evidence of the mildness and aseptic condition of the atmosphere, and show how such a fatal disease as pneumonia can be successfully treated in this climate. The patient, a young man, twenty-two years of age, had been working on street paving. On the night of May 2d he had the initial chill and pain on his right side below the nipple. He was very anxious to keep at his work, and did so until the 8th instant, when, almost exhausted and greatly emaciated, he consulted me for shortness of breath and soreness of the right side of his chest. On examination I found there was consolidation of the whole of the right lung. He never kept his bed, but passed most of the day out in the open air, sitting in the park, as he lived only one block away, and walked to my office every day, a distance of three blocks. He gradually recovered, and in the course of four weeks he went to work again as well and strong a man as ever.

Destruction of an Anatomical Museum.—In Madrid, recently, fire destroyed the greater part of the Museum of Anatomy attached to the University.

## CLIMATIC TREATMENT OF CONSUMPTION.

By H. D. NILES, M.D.,

SALT LAKE CITY, UTAH.

The pretty general acceptance of the germ-theory of Koch, and the encouraging progress made in climato-therapeutics during the past few years have given a new and strong impetus to the study of the treatment of phthisis. And when an effective germicide, which may be safely and easily applied to pulmonary cavities shall have been discovered, and each factor of a climate shall be capable of mathematical computation, and its therapeutical effect accurately determined, it is believed we will be provided with formidable weapons with which to cope with this much-dreaded disease.

If this much has not yet been accomplished, enough has been done to show some of the errors of the past and to promise a more hopeful treatment for the future.

The great majority of the medical profession, even those who are not quite prepared to believe in the bacillar origin of phthisis, or who do not fully accept the remarkably favorable clinical evidence from the high-altitude resorts, are agreed on the following points: 1. The importance of local treatment has been underestimated in the past. 2. Preventive treatment has not received the attention it deserves. 3. In the general treatment too much reliance has been placed on drugs.

While fully appreciating the usefulness of proper medicinal treatment, hygienic surroundings, correct habits, and especially appropriate exercises, the object of the present paper is mainly to show how nearly a well-chosen climate may meet these recently modified views of treatment, and to make suggestions on the selection and adaptation of a climate to cases of lung disease.

The writer believes the following conclusions hold good at the present time:

1. More effective than any available medicinal application is the continuous inhalation of the nearest aseptic and the most absorptive air possible, of even temperature, free from irritating impurities, sufficiently rarefied to distend and reach every part of the lung and gradually produce increased chest capacity.

2. In the treatment directed to the general improvement of the phthisical patient proper climatic surroundings are first in importance. A place should be selected where the air is pure, light, bright, bracing, tonic—even exhilarating—and of even temperature, where the greatest inducements, as well as opportunities, are offered for outdoor life amid new and attractive scenes.

3. A place possessing precisely the opposite of those climatic conditions most favorable to the production of phthisis is the one to be chosen for the residence of those in whom there exists an inherited or acquired predisposition to this disease.

*Prevention of Phthisis.*—The advisability of early seeking a proper climate by those who are predisposed to consumption needs only to be mentioned here. Nor is any argument needed to prove that as low, moist, warm places are most favorable to the development of phthisis, a residence in a high, dry, cool place should be advised where such a tendency exists. As this class of prospective invalids more fully appreciate their increased risk in unfavorable surroundings they will be more willing, in spite of business or social interests, to take every precaution, and as the physician's knowledge of climato-therapeutics becomes more precise he will be more positive in his counsel, and the preventive treatment of phthisis will be as popular in practice as it is now in theory.

*Local Effete of High-altitude Climate.*—The nearest approach to that air which has been described as the best local application available for diseased lungs is found only in high, dry places. For it is here that the atmosphere is the nearest aseptic, and possessed of the greatest absorptive properties. Its coolness, equability, purity, freedom from dust, fog, vapors, and smoke depending upon other

conditions, which also exist in favorably located high-altitude places.

Until an easier and more effective method of introducing an efficient germicide into the lungs is found than that by pulmonary injections or gaseous enemata, or inhalations of medicated vapors, sprays, or air, it is believed that as much or more good may be accomplished by placing the patient where the lungs are continuously bathed in an air possessing naturally precisely the same qualities (if not in quite the same proportions) that we would artificially produce.

The aseptic and absorptive properties of the atmosphere peculiar to dryness, coolness, and altitude are too well known to need explanation here. The following tables, however, may serve to give an approximate idea of the markedly different degrees of strength of these qualities in different locations. Table A shows the number of bacteria in ten cubic metres of air, taken as nearly as possible at the same time in June, 1883, at the respective places, by Professor Miquel.

*Table A.*

| | |
|---|---|
| At an elevation of from 2,000 to 4,000 metres..... | None |
| On the Lake of Thun, 560 metres..... | 8 |
| Near the Hotel Bellevue at Thun..... | 25 |
| In a room of Hotel Bellevue..... | 600 |
| In the Park of Montsouris (near Paris)..... | 7,600 |
| In Paris itself (Rue de Rivoli)..... | 55,000 |

In Table B, Dr. Denison's method of computing the vapor transpiration of the same person in the different places, varying in coolness and dryness, is used.

Jacksonville, Colorado Springs, and Salt Lake City are compared in this way in the case of a man who, we will assume, breathes 500 cubic feet of air in twenty-four hours, dew-point of expired air being considered 94° F., Glaisher's estimate of weight of vapor at saturation of air of given temperature being adopted.

*Table B.*

It is only fair to add that the increased respiratory activity induced by the rarefied air and greater amount of exercise usually taken in high, dry places would make the difference in transpiration still greater. Denison estimates that one breathes about twenty per cent. more air in Denver than in Jacksonville with the same amount of exercise.

The investigations of Dr. Denison and Professor Miquel not only prove conclusively the existence of remarkable aseptic and absorptive qualities of certain airs, but they pretty clearly indicate the climatic conditions most favorable for the development of these qualities. This knowledge, combined with that of the attested value of antiseptics and absorbents in the treatment of wounds generally, and that afforded by the researches of Koch, lead us to believe that in air possessing these qualities we may have a most valuable local application for diseased lungs. Regarding this air as a local application to an inflamed discharging surface, characterized by the presence of a specific germ, it should be remembered that the other climatic factors have an important bearing on the remedial effect of such an application.

1. Equability acts the negative part of preventing the irritation liable to ensue from sudden changes in the temperature of the application, and thus overbalancing the good effects of dryness.

2. Rarefaction of the air, by its effect on the vaso-motor system, tends to relieve any passive congestion of the lungs. By increasing the depth and number of the respirations it not only mechanically distends the weakened and diseased portions of the lungs, but brings them into contact with a greater amount of dry aseptic air. The secondary effect of this regular and continuous expansion is to permanently increase the chest capacity.

3. The greatest number of bright, cloudless days gives the greatest opportunity for out-door life and exercise, with a resulting augmentation in the amount of dry aseptic air inspired.

4. Wind- and sand-storms render the air irritating, and the respirations shallow, depressed, and irregular. Their absence has a negative value similar to equability.

5. Cold enhances the aseptic and stimulating qualities of dry air.

*Effect of Climate on General Condition of Patients.*—The climatic conditions described as the most conducive to the improvement of the general health are also to be found only in the high altitudes. Dryness, brightness, and rarefaction of the air and abundance of sunshine belong to all very high places. From among these a location should be selected where the remaining desirable qualities are found.

It is difficult for one who has never experienced the effects produced by coming from a low to a very high place, to understand the wonderful exhilaration that follows breathing this dry rarefied air. Those in health feel and enjoy the powerful tonic, almost intoxicating, effect, but not to the marked degree that the invalid does. It seems to supply a necessity in his case. Nor are the effects limited to a temporary stimulation, to be followed by a corresponding depression. Very soon his appetite is better, his digestion improves, the feeling of lassitude disappears, exercise becomes a pleasure, and he is able to thoroughly enjoy the out-door life to which he is invited by new scenes, sunny skies, and a bracing air. With the increased exercise there is a more rapid gain in weight and strength.

These are the usual effects in appropriate cases, the improvement being modified by, as well as modifying, the local part of the trouble.

While all observers are agreed that these are the ordinary results to be expected in appropriate cases, there are differences of opinion as to just how they are produced. Undoubtedly the strength of the circulation and the greater determination of blood to the periphery induced by the lessened atmospheric pressure favor greater functional activity of all the internal organs by relieving local passive congestions. The heart's action, which may at first be accelerated, is always stronger, and the respirations, at first more rapid, become deeper. Hence there is a more perfect oxygenation of the blood. (It is possible also that this attenuated air yields up its oxygen more readily than the denser air of low places.) With all of the internal organs relieved of venous engorgement, and the surface and lungs supplied with blood in a larger quantity, the conditions are most favorable for healthful activity of the organs engaged in digestion and assimilation, and the improvement of the general nutrition, as well as for the repair of the local damage to the lungs. The increased muscular and nervous energy, and the better work done by the excretory organs may also be attributed to a purer and more generous supply of blood.

The abundance of sunshine characteristic of high-altitude places, aside from permitting and encouraging much-to-be-desired out-door life, has a direct salutary effect upon the health and spirits of the invalid.

If the theory thus briefly outlined be the one accepted,

and the stimulus of the lessened atmospheric pressure upon the vaso-motor system be accredited with the chain of good results that ensue, it is evident that the two most important points upon which the physician should satisfy himself in each case before recommending a change are: Is the heart capable of promptly responding and readily adapting itself to an increased rarefaction of the air? If so, what elevation would be safe as well as efficient?

It should be remembered that an adaptability of the heart to a very high altitude may usually be acquired by gradually increasing the elevation, and an altitude entirely unadvisable, and even hazardous, at first, may become in time the one most desirable. In the past there has been a tendency on the part of physicians to advise or permit their patients to seek an altitude altogether too high to commence with. Experience has taught that elevations of three thousand feet to six thousand feet should include nearly all cases, with the greatest number in places of less than five thousand feet above the sea-level. Undoubtedly, if more caution was exercised in this regard, and greater care shown in selecting places as free as possible from sand- and wind-storms and sudden changes in the temperature, the tabulated clinical reports of the treatment of phthisis in high-altitude resorts would read even more favorably than they now do. The prevalence of these storms, and the marked variability of the temperature, so common in many high-altitude resorts, are always objectionable features, and many times are insurmountable obstacles to a residence in an otherwise healthful climate.

They lessen the number of days suitable for open-air pursuits, and even indoors no amount of precautions are sufficient to perfectly guard against their ill effects.

It would therefore appear that the requisites of a climate for pulmonary invalids are:

Altitude (3,500 feet to 6,000 feet).
Dryness (greatest possible).
Equability.
Greatest number of sunshiny days.
Greatest possible freedom from sand- and wind-storms.
Comparative coolness.

Possessing all of these attributes, there are still other factors which need only to be mentioned here, but which should have no light weight in influencing our estimation of a health-resort, viz., the sanitary surroundings, the hotel accommodations, the completeness of the change, and its attractiveness. If a city is selected, it should be one where the streets are wide, the houses far apart, and where the invalid need be deprived of none of his accustomed luxuries, comforts, and conveniences.

*Selecting a Climate.*—We have thus briefly presented our idea of the best climatic treatment for phthisis, and of the method by which a high-altitude climate produces its beneficial effects, and have indicated the most important attributes which should characterize such a climate. While altitude should vary according to the individual requirements and adaptability of each case, the other factors mentioned are desirable in all cases.

The so-called "ideal climates," or climatic specifics for phthisis, do not exist. Not only that, but it is certain that in the most favored localities (climatically) consumption may occur as the result of bad hygienic surroundings, mode of living, habits, etc. A residence in none provides immunity from this dreaded malady, or promises a certain cure for all cases. Neither is it possible to find with each different altitude suitable for different cases a perfect combination of all the other climatic factors most desirable. We must choose that place which, being the proper altitude, most nearly fills the other requirements. For example, wind, dust, and variability belong, to a greater or less extent, to almost all very high places; yet among places of equal altitude there is a marked difference in these respects well worth our consideration in estimating the comparative merits of a resort.

A critical study of each climate and of each case will enable us to more perfectly adapt the one to the other, and we may then confidently expect better results than by the plan so much in vogue at present of recommending a favorite resort in all cases, simply on account of its popularity. In deciding upon a given climate it is believed that reliable statistical data should rank first, clinical observations second, and the opinions and impressions of those who may be prejudiced advocates of a certain resort last in importance in influencing our conclusions.

*Contra-indications.*—The contra-indications to the employment of a high-altitude residence are based on the inability of the patient to bear and respond to the stimulus of the rarefied air to the vaso-motor and respiratory systems.

The success of this treatment depends upon the patient having some general recuperative power, a sufficient amount of healthy lung-tissue, and a heart in which degenerative changes have not started. Large amount of lung structure involved, extensive pleuritic adhesions, fatty or parenchymatous degeneration of the heart would be contraindications; while the age, constitution, and temperament of the patient, amount of emaciation, fever, etc., would guide us in estimating the vital powers. Too often the change is attempted as a *dernier ressort.* The fatal issue is sometimes hastened in those cases known to be hopeless which are sent to the altitudes for relief.

A clear comprehension of the *rationale* of the high-altitude treatment, accuracy in diagnosis, sound judgment in estimating the general and local recuperative powers in each individual case are worth more than any fixed rules that shall have a general application. But in all cases of phthisis that are remediable or curable by any treatment, it is believed, unless there be positive contra-indications, that a residence in a well-chosen high altitude is to be advised.

*In Regard to Salt-water Bathing.*—Many strumous patients have derived much benefit from residence near the sea and salt-water bathing; and the medical profession have long recognized the value of this plan of treatment in such cases. Its success in strumous lung troubles has doubtless given the coast much of its reputation as a resort for the phthisical. The majority of cases of caseous phthisis, chronic bronchitis of children, and almost all scrofulous diseases of the respiratory tract are unquestionably favorably influenced by sea-air and sea-water, notwithstanding the bad climatic surroundings in other respects. But is it not reasonable to hope for a more certain and a greater improvement where to this treatment is added all of the advantages of a high-altitude resort. Impressed with this idea the writer has been engaged for some time in collecting notes of appropriate cases at The Great Salt Lake, Utah, where such a combination apparently exists. These notes, when complete, will be submitted to the profession.

---

COLORLESS STOOLS IN UNJAUNDICED PERSONS.—From a study of this subject Dr. Walker concludes: 1. That the form of hydrobilirubin, the coloring matter of the fæces, depended on the mutual reaction of the bile and pancreatic fluid, under the influences met with in the intestinal tract. 2. That in disease a deficiency of pancreatic fluid would, equally with a deficiency of bile, cause the pathological condition of colorless or clay-colored stools. 3. That as, according to the most recent physiological researches, that portion only of the colored constituents of the bile which had been converted into hydrobilirubin was excreted in the fæces, while the unchanged bilirubin, and biliverdin were absorbed, it followed that if hydrobilirubin could not be produced without the aid of the pancreas, that organ must have an important rôle in regulating what proportion of the bile entering the intestines should be absorbed and what thrown off in the fæces. —*The British Medical Journal.*

## CASTOR-OIL AS A MENSTRUUM FOR COCAINE.

By S. MITCHELL, Jr., M.D.,

HORNELLSVILLE, N. Y.

The use of cocaine dissolved in castor-oil may not be to many such a novel method of employing this valuable agent as it was to me. I do not remember, however, to have heard of its previous use, and the idea only occurred to me in the dire extremity when seemingly I had exhausted all the remedies that were at all applicable, and my patient was "nothing better."

I trust the publication of the following details of the case wherein I first employed the above remedy may be of interest and perhaps profit to others.

Mr. H——, aged fifty, whom I was treating for chronic aural catarrh, was suddenly attacked with herpes zoster, covering the whole left side of the head from the temporal ridge to the occiput. Nearly the first vesicle to form was in the conjunctiva of the upper lid of the left eye. It was attended with much pain, great congestion of the whole palpebral and ocular conjunctiva, contraction of the pupil, and sluggishness of the iris. Atropine and cocaine were employed during the whole course of the disease, and the eye thus kept quite comfortable, until the disappearance of the vesicles from the head. As they healed, leaving deep and painful cicatrices, the one in the conjunctiva healed also, leaving a hard cicatrix that at once assisted in forming an ulcer in the lower margin of the cornea, as large as a kernel of wheat, that steadily grew deeper and more painful, despite all remedies employed. At the end of a week there was well-marked chemosis, together with deep-seated and constant pain. At this juncture it occurred to me to try a drop of castor-oil in the eye, if possible by its use to mitigate the terrible rasping the hard cicatrix was inflicting upon the cornea; then the happy idea suggested itself to combine cocaine with the oil. A five per cent. solution was made, dissolving the cocaine in the oil by means of gentle heat. A few drops of this were instilled into the eye, with almost magical effect. Pain was at once greatly mitigated, the chemosis disappeared, the cornea cleared up, the ulcer began to heal, and my patient grew happy and smiling. All other remedies were discontinued, recovery being rapid and complete.

## A CASE OF INTESTINAL OBSTRUCTION.

By DEWITT C. RODENHURST, M.D.,

PHILADELPHIA, N. Y.

On May 26th I saw William R——, aged two and a half, who was vomiting and had had no movement of the bowels for two days. I gave calomel and bicarbonate of soda as a cathartic, and bismuth and oxalate of cerium for the vomiting, but without result. On the following day the symptoms were the same. I ordered ten grains of calomel, which controlled the vomiting, and then gave an enema with an eighteen-inch rectal tube, and am positive that the tube went sixteen inches into the bowel, as I was able to trace it through the abdominal wall. With this enema came quite a quantity of greenish mucus. I repeated the enema in four hours with the same result, and I now became convinced that there was intestinal obstruction. The next morning Dr. Abell, of Antwerp, saw the case with me, and confirmed my diagnosis. We then put the child on ten-drop doses of tincture of opium, per rectum, every four hours, giving at the same time about one ounce each of beef-extract and milk, and once in about twelve hours giving the large enema with the rectal tube. There was no vomiting this day. The same treatment was continued for two days, and condition remained about the same.

On May 30th the child began to show signs of failure, and on the following day Dr. Willis E. Ford, of Utica, N. Y., was called, with an idea of surgical interference, as it had become evident that the child must die without.

Dr. Ford brought with him a Bergeon apparatus for gaseous enema, and proposed inflating the intestines with carbolized, sulphuretted hydrogen gas, after the method introduced by Dr. N. Senn, of Milwaukee, Wis.

The gas-bag of the Bergeon apparatus holds five gallons. It was filled, the child being well under chloroform, and the gas was gradually pumped into the intestine, the anus being firmly held to keep it from escaping. The large intestine soon being inflated, the gas began to pass the ileo-cæcal valve, and in a brief space of time there was an audible sound, as of something giving way.

We suggested that the obstrution, which without doubt was intussusception, was removed, the anus was let go, and following the escape of the gas there came fæces of such a character as to assure us the obstruction was removed.

The child was kept under the influence of morphine for forty-eight hours, and then given a large dose of castor-oil, after which followed a natural stool. From May 28th till the operation the temperature of the child ranged from normal to 100⅘° F.; the pulse ranged from 90 to 120. There was no vomiting after the ten-grain dose of calomel was given till the 30th, and then the vomited material was only what the child had been allowed to take. There was never any tenderness or bloating of the abdomen. There was no tumor to be felt.

During all the time the child, when not asleep, would ask for drink, answer questions, notice playthings, and in no way seemed sick except that he wanted to lie in bed and would take no nourishment. Before his sickness his habits had been the same, except that he had developed the idea of climbing. This, I believe, is the first time this operation has been performed in New York State, as I can find no record of it before.

## A YOUNG LIVING FŒTUS.

Dr. T. T. Kirk, of Pittsburg, Pa., writes: "I had a case similar to Dr. J. L. Nascher's, reported in The Medical Record of June 15th. My patient, Mrs. C——, aborted October 15, 1888. She menstruated November 15, 1888. I was called hurriedly on May 2d, and found a head presenting. The next pain brought a small living fœtus, with closed eyes, no hair, finger- or toe-nails. In a few seconds it gasped and cried. The nurse wrapped it in cotton and fed it on sweetened water. Allowing one week after the menses began, the child was five months and ten days old. It was born before 5 P.M., and lived till after 3 P.M. the next day—over twenty-two hours."

A Question of Immense Importance.—The General Medical Council of Great Britain seems to be a body of great importance, or at least so considers itself. Among other mighty subjects engaging its attention, at a recent meeting, was that of precedence as between its president and those of the Colleges of Physicians and of Surgeons, respectively. The question had arisen lately in connection with a work in which they were jointly engaged. The Council appointed a deputation to wait upon the Lord President of the Privy Council in reference to the matter, but the result of their interview proved inconclusive. It was therefore resolved that the President of the Council be requested to frame, together with the solicitor to the Council, a petition to the Queen to request Her Majesty to determine the order of precedence of the President of the Medical Council and the heads of the other bodies concerned in the administration of the medical acts.

## THE FATHER AND THE RACE.

A CONTROVERSY has been going on in *The Forum* regarding the relative importance of woman in influencing the development and character of children and of the race. Professor Lester Ward, reasoning from various zoological data, concludes that woman is the race and that man is only a necessary adjuvant, who performs the duties of impregnating the ovum and supporting the progeny. All moral, intellectual progress comes through the woman. Hence it is inferred that the most essential duty of modern civilization is to promote the moral and intellectual welfare and progress of the mothers.

This chivalric view is directly antagonized by Mr. Grant Allen, who, by a like appeal to zoology and embryology and the facts of heredity, tries to prove that woman is the appanage and man the chief factor of existence. Woman, he says, is simply or mainly set apart for purposes of perpetuating the race. The duties of maternity make too severe a strain upon her energies to enable her to compete with man in those labors which advance knowledge and improve the condition of mankind.

We think there are very few who will not agree in the main with Mr. Allen's argument. Without discussing it now, however, we wish to bring to our readers' attention an interesting contribution to one phase of this subject, in the shape of a monograph on the influence of the father upon the development of the fœtus, by Dr. Félice La Torre.[1]

The general tenor of Dr. Torre's work is to show that a decided preponderance of influence upon the child is exercised by the father. There is, he says, no single thing which so influences the health and development of the fœtus as the constitutional condition of the father. To have children strong and well, it is necessary that the father be sound in health; the mother may be an invalid or not. Quoting Boinnet, he adds, "I have shown by my tables of family histories that the axiom, *Pater est quem morbi filiorum demonstrant*, has more of certainty than the adage, *Pater est quem nuptiæ demonstrant*." Dr. Torre's concluding sentence is "*Talis pater, talis filius.*"

Dr. Torre's views are supported by a record of one hundred cases, which he analyzes and tabulates.

[1] Des conditions qui favorisent ou entravent le développement du fœtus. Influence du père. Recherche clinique, par le Dr. F. La Torre. Paris: Octave Doin, 1888.

While his deductions are not absolutely conclusive, they appear to show that if, when a marriage is contracted, the father is weak in body or suffering from a constitutional ailment, there is less chance of the children being vigorous than if the mother were in such condition.

While Dr. Torre's investigations cover chiefly the subject of the influence of the father upon the physical condition of the child, they supplement in a measure the studies of De Candolle, who showed that distinctive traits are more often transmitted by fathers than mothers; more particularly the higher intellectual faculties.

## CHEMICAL STRUCTURE AND PHYSIOLOGICAL THERAPEUTICS.

THERE is no field of medical activity at present more interesting and fruitful than that which concerns itself with the application of new chemical compounds to therapeutics. The work here is not purely an empirical testing of miscellaneous drugs, but is conducted, in a considerable measure, on carefully laid-out plans based upon chemical and physiological knowledge.

Dr. Lauder Brunton has recently delivered a series of lectures upon the relationship between chemical structure and physiological action, in which he has shown the guiding principles adopted or to be adopted in the search for new remedies.

Dr. Brunton has gone over a very wide field, for he passes in review a good many elementary facts of chemistry as preliminary to the consideration of his subject proper. We cannot attempt, therefore, to give any systematic summary of his lectures, but only to refer to some of the more interesting points that he brings out.

The causes of disease are first considered. The lecturer dwells at some length upon microbes, microbic ferments, ptomaïnes, and leucomaïnes. He shows that microbes often cause morbid phenomena, not by their direct action but by certain ferments which they produce, or through the poisons known as ptomaïnes.

The fact that ptomaïnes are present in decaying meat would lead one to suppose that poisoning from this source would not be infrequent. Its comparative rarity is thought to be due to the fact that mixed bacillary products are often very poisonous, while pure single cultures are not. This would explain the especially poisonous character of meat, in which if diseased there may be the products both of a pathogenic and a putrefactive bacillus.

Dr. Brunton is inclined to accept the views of Roux and Yersin, that the diphtheritic poison belongs to the ferments and can, therefore, act even after the microbe which produces it is killed.

After giving a short history of the ptomaïnes, the lecturer says that a number of them belong to the compound ammonias. The most common of the ptomaïnes, viz., choline, neurine, and muscarine, belong to this class; and they all have one common property, namely, that of stimulating glandular action and involuntary muscle fibres; their action is antagonized by atropine, and it is suggested that this drug be used in poisoning from tainted meat and fish.

One prolific source of disease is microbic action and chemical decomposition in the intestine. In the treatment of disease from this cause there are three indications — to eliminate by purgatives, to antagonize by

antiseptics, and to starve out the bacteria by changes of diet.

The search for intestinal disinfectants has so far not been very successful. Brunton quotes Pellicani as saying that substances containing a diphenyl nucleus are less poisonous and more antiseptic than those containing a single phenyl nucleus. The use of sulphates with phenol makes the latter less poisonous, while the sulphonic compounds, like aseptol, and the compound of beta-naphthol and salicylic acid, known as betol, are suggested as likely to be very efficient. In the matter of starving out bacteria, the lecturer commends the plan of stopping milk altogether in infantile diarrhœa, and he discountenances farinaceous foods in typhoid fever.

Following up the subject of microbes and disease, the treatment of phthisis by antiseptics is considered. Without laying great stress on this subject, he speaks favorably of the principle of gaseous injections, and recommends the use of helenine, and of phenyl acetic and phenyl propionic acids, because of their specially destructive influence upon the micro-organism.

When microbic action takes place in the blood and tissues, as in anthrax, tetanus, rabies, diphtheria, and certain other infectious diseases, we cannot expect to reach the trouble by antiseptics. In such cases purgation, diuresis, and washing out the system with copious draughts of water ought to be resorted to.

Dr. Brunton discusses in an interesting way the subject of preventive inoculations, in which he thoroughly believes. He cites the work of Pasteur for rabies and anthrax, that of Chantemann and Vidal for typhoid fever, that of Roux and Chamberlain for septicæmia, and that of Roux and Yersin for diphtheria.

Dr. Brunton discusses the relation of chemical structure to antiseptic power, and also to analgesic and antipyretic action. The subject is too much involved in chemical details to enable us to present it here. We quote, however, his final words with regard to the prospects and dangers of analgesics:

"As the ways in which methyl may be combined with aromatic bodies are almost numberless, we may expect before long a great increase in the number of analgesics, and not improbably some new ones may far surpass in their power to relieve pain anything that we as yet possess. Before passing from this subject, however, I must indicate a possible source of danger from the continued employment of such analgesics.

"We know that the continuous employment of narcotics, such as morphine or chloral, is apt to grow into a habit, and the consequences may be very deleterious to the mental functions. A similar habit, we know, may be established by the use of cocaine, and it is possible that something similar may occur in the case of other analgesics. But there is another possibility which I wish to indicate in addition to this, namely, that just as the brain may become deteriorated by the use of chloral or morphine, so the cord may possibly be injured by the use of analgesics. I have already mentioned that Dr. Cash and I observed in frogs symptoms resembling those of disseminated sclerosis, or of locomotor ataxy in man, and Batten and Bokenham have noticed that antipyrin may produce in frogs a condition like that of spastic paralysis. Cash and I tried to produce symptoms of permanent disease of the spinal cord in frogs by keeping up the poisoning for some time. We were unsuccessful in the attempt, as the symptoms always passed off when the poison was eliminated, but still the conditions in our experiment were very different from those which would occur from the prolonged use of analgesics by a patient, inasmuch as the treatment of the latter might continue for weeks, months, or years, whereas in our experiment time could be counted by days."

## MITHRADATISM.

MEDICAL writers have for some time been conscious that medical literature needed a new word to express the artificial production of immunity against disease. When small-pox was the only infection which could be avoided by preparing the system against it, the term vaccinate and vaccination answered very well. But we cannot say that we "vaccinate" against rabies, or anthrax, or, in other words, we have no general equivalent for that verb.

We believe that it is Professor E. Ray Lankester who has come forward in this emergency and proposed the term "mithradate" and "mithradatism." This word is taken from the name of the Phrygian King Mithradates, who lived about 100 B.C., and who is credited with having so thoroughly saturated his system with poisons that he was proof against any of them.

Accepting Professor Lankester's suggestion, we could speak of Pasteur as mithradating patients bitten by rabid dogs, or mithradating sheep against anthrax; and we could speak of the unsuccessful attempts of Ferran to mithradate against cholera, and of Freire's firm belief in the mithradating power of his yellow-fever cultures. The name of the process would be "mithradatism;" and the name of the thing, corresponding with "vaccine," would be "mithradatine."

We submit Professor Lankester's new word to the suffrages of our readers, only regretting that he could not have found some ancient and toxibund Phrygian who had a little more euphonious name.

# News of the Week.

THE LEGAL RIGHT TO DISCIPLINE PHYSICIANS.—Under this title the *Sun* gives a review of a case which has recently much occupied the attention of English physicians. The plaintiff was a physician named Allbutt. The defendant was the General Council of Medical Education and Registration of the United Kingdom of Great Britain and Ireland. The Council is a public corporation empowered by law to keep a register of qualified medical practitioners, and to cause it to be printed and sold, so that the public may be correctly informed what physicians are and are not on the list. Only those doctors who are duly registered are entitled to sue for their charges, or to give certain medical certificates provided for by law. The council is expressly authorized to erase from the register the name of any physician who shall be convicted of any crime, or who shall, after due inquiry, be adjudged by the council "to have been guilty of infamous conduct in any professional respect." Such erasure, however, does not absolutely prevent the doctor whose name is erased from practising medicine. He is debarred from collecting his bills by suit, and from giving medical certificates under

the statute; but he may still be employed by patients, or called in consultation by other physicians. The name of Dr. Allbutt was on the register, and was erased by the General Council upon the ground that he had been guilty of infamous conduct as a professional man in causing to be published and sold a certain book, the publication and sale of which was detrimental to public morals. The plaintiff asked the court for a writ of mandamus commanding the Council to restore his name to the register, and also sought to recover damages against the Council for libel, because in its published minutes the fact of the erasure and the reason therefor had been stated. The case thus presented two questions: First, whether a physician whose name has been stricken off a list of medical practitioners by the corporation authorized to keep such list can compel that body to restore his name, when it was removed for a cause and in the manner prescribed by law; and, secondly, whether it is libellous to publish a statement that the name has been erased, together with the reason for such erasure. The Court of Appeal has answered both questions in the negative. In this connection, a Massachusetts case of somewhat similar character is cited. Dr. Ira Barrows was expelled from the Massachusetts Medical Society for "gross immorality," in having broken a promise to Dr. Benoni Carpenter, to whom he had sold his practice at Pawtucket, for a large sum. The promise appears to have been an assurance that he would not resume practice in the same locality; but he returned to Pawtucket, and entered upon professional work there again in the course of a year. An article relating to his expulsion was published in the *Boston Medical and Surgical Journal* by Luther V. Bell, and the doctor thereupon sued Bell for libel. Chief Justice Shaw held that the suit could not be maintained.

Medicine and the Stage.—In Mr. Henry Irving's speech at the festival dinner to Sir Morell Mackenzie, of the Golden Square Hospital for Diseases of the Throat, he said that "there had always been a deep sympathy between actors and doctors, but he did not know why, unless the doctors regarded the players as a little mad. Actors were on the free list of the doctor's skill."

The Effect of Continence on Adults.—Dr. Brown-Séquard says: "It is known that well-organized men, especially from twenty to thirty-five years of age, who remain absolutely free from sexual intercourse or any other causes of expenditure of seminal fluid, are in a state of excitement, giving them a great, although abnormal, physical and mental activity."

Brown-Séquard's Testicular Injection. — Dr. Brown-Séquard gives, in *The Lancet*, the following account of the technique of his injections: "I have made use, in subcutaneous injections, of a liquid containing a small quantity of water mixed with the three following parts: First, blood of the testicular veins; secondly, semen; and, thirdly, juice extracted from a testicle crushed immediately after it has been taken from a dog or a guinea-pig. Wishing in all the injections made on myself to obtain the maximum of effects, I have employed as little water as I could. To the three kinds of substances I have just named, I added distilled water in a quantity which never exceeded three or four times their volume. The crushing was always done after the addition of water. When filtered through a paper filter, the liquid was of a reddish hue and rather opaque, while it was almost perfectly clear and transparent when Pasteur's filter was employed. For each injection I have used nearly one cubic centimetre of the filtered liquid. The animals employed were a strong, and, according to all appearances, perfectly healthy dog (from two to three years of age), and a number of very young or adult guinea-pigs. The experiments, so far, do not allow of a positive conclusion as regards the relative power of the liquid obtained from a dog and that drawn from guinea-pigs. All I can assert is that the two kinds of animals have given a liquid endowed with very great power. I have hitherto made ten subcutaneous injections of such a liquid—two in my left arm, all the others in my lower limbs—from May 15th to June 4th last. The first five injections were made on three succeeding days with a liquid obtained from a dog. In all the subsequent injections, made on May 24th, 29th, and 30th, and June 4th, the liquid used came from guinea-pigs. When I employed liquids which had passed through Pasteur's filter, the pains and other bad effects were somewhat less than when a paper filter was used."

German Physicians Adopt a Code of Ethics.—On June the 24th the seventeenth Congress of German Physicians met at Brunswick, and passed the following resolutions: "1. Every kind of public laudation, whether it proceeds from the physician in question himself or from others, and continued advertising in public papers are to be reprobated. 2. The designation 'specialist,' for puffing purposes, is to be reprobated. 3. The public offering of medical assistance gratis, underbidding in concluding contracts with sick societies and the like, offering advantages of any kind to a third person in order to procure practice, are inadmissible. The designations 'Klinik' and 'Poliklinik' (hospital) belong exclusively to institutions which serve the purposes of instruction in connection with universities. 4. The ordering and recommending secret remedies are inadmissible. 5. Any attempt of any kind on the part of a physician to intrude upon the practice of another is dishonorable, especially in the case of one who has acted as substitute or in consultation. A practitioner must by no means undertake the treatment of the case without the express assent of the previous physician. A specialist called in for a definite part of the treatment must strictly confine himself to that. 6. No physician is at liberty to make disparaging remarks to others about another physician."

The Pennsylvania State Medical Society has postponed its annual meeting until next year.

Abolishing the Scottish Medical Faculties.—A Member of Parliament has introduced a resolution to abolish the Faculties of Medicine in the Scottish Universities.

Flags to Announce Confinements.—French medical journals state that a flag will be displayed at the Medical Department of the University of Paris whenever a confinement is in progress in the Obstetrical Ward. The color of the flag will indicate the kind of confinement: a blue flag indicating that the confinement is a simple one, a yellow flag that the labor is difficult, and a green flag that an operation is necessary.

His Royal Highness the Duke of Bavaria, M.D., has just done his one thousandth cataract operation. We should like to know his per cent. of failures.

Sir Andrew Clark recently gave a reception to Dr. Tholozan, physician to the Shah of Persia.

The American Rhinological Association will hold its Seventh Annual Meeting at Chicago, August 28th, 29th, and 30th. The Committee on the Examinations of the Inmates of Insane Asylums will make their report on "The Relations of Rhinal Inflammations to Mind Affections" at this session.

Dr. DeWolf has resigned as Health Officer of Chicago, after thirteen years of most efficient service.

The Death of Dr. Charles Elam, a distinguished London physician and writer, is announced. Dr. Elam was in his sixty-fifth year.

Trusteeing Drunkards.—The German Medical Congress has recommended that drunkenness be recognized as a reason for placing a person under trustees.

The daily papers announce the following: Tozoni, the sculptor, has finished an excellent bust of the late Dr. John Swinburne, the philanthropist.

Dr. Grissom Acquitted.—The trial of Dr. Eugene Grissom, Superintendent of the Asylum for the Insane near Raleigh, N. C., before the Board of Directors, has been concluded. The charges were preferred by Dr. Lion H. Rogers, Assistant Physician, and John W. Thompson, Steward, and were of gross immorality, cruelty, and misappropriation of property of the asylum. The investigation consumed four weeks, and Dr. Grissom was acquitted on every charge, the vote being 6 to 2, except as to the charge of immorality, and on that it was 5 to 3. The sensation of the trial was the introduction by Grissom of a compromising letter written by Dr. Rogers to Miss May Mendenhall, a former female attendant.

Alonzo Clark Scholarship.—By the will of the late Alonzo Clark, M.D., LL.D., it was placed in the power of the Faculty of the New York College of Physicians and Surgeons to bestow a scholarship, with an income of about nine hundred dollars a year, for the purpose of promoting the discovery of new facts in medical science. This has been bestowed, for three years from October 1, 1887, upon T. Mitchell Prudden, M.D., of New York City.

The American Association of Obstetricians and Gynecologists will hold its next annual meeting at the Burnett House, Cincinnati, O., on Tuesday, Wednesday, and Thursday, September 17, 18, and 19, 1889. No formal invitations will be issued to non-members, but the Association extends an invitation to all members of the profession who may feel interested in this branch of medical work to attend the meeting and participate in the proceedings. The papers and discussions will embrace subjects pertaining to obstetrics, gynecology, and abdominal surgery.

Dr. Lewis A. Sayre has recently been elected an honorary member of the St. Petersburg Medical Society, one of the largest and most important of the Russian societies. Dr. Sayre returned a few weeks ago from his trip to the Hot Springs of North Carolina, much improved in health.

Execution by Electricity.—A London cable despatch says: The investigation in New York in the case of the murderer Kemmler, as to whether or not electricity can be relied upon to cause a prompt and painless death, is being watched with considerable interest on this side of the water. A correspondent of the *Pall Mall Gazette* writes to that paper to say that, whatever doubt exists in America, there is hardly room here to question the certainty of the results of electricity scientifically applied. Killing, he says, by electricity, has been reduced to absolute scientific certainty by the experiments of Dr. B. W. Richardson in his model abattoir at Croydon.

Chloroform.—Some time ago the Hyderabad Commission of India made a report extremely favorable to the use of chloroform as an anæsthetic. There having been some criticism made upon this, the Nizam of Hyderabad has telegraphed to *The Lancet* offering to place the sum of $5,000 at the disposal of *The Lancet* for the purpose of sending commissioners to India to investigate the matter. The Nizam shows his faith in the anæsthetic for his Indian subjects.

Dr. John B. Roberts has been elected Professor of Surgery in the Woman's Medical College of Philadelphia, to succeed Dr. W. W. Keen, resigned.

Dr. Charles B. Nancrede, of Philadelphia, has just been elected Professor of Surgery in the University of Michigan, Ann Arbor.

Bologna, following the initiative of Milan, opened, on June 30th, an Instituto Anti-rabbico, or institution for the treatment of rabies on the Pasteur method. The King, the Prime Minister, and the various civic and scientific bodies, as well as the townsfolk of Bologna, contributed the requisite funds. Every considerable Italian city will soon, it is anticipated, be provided with an institution of the kind.

The American Public Health Association will hold its Seventeenth Annual Meeting at Brooklyn, N. Y., on October 22, 23, 24, and 25, 1889. The Executive Committee have selected the following topics for consideration at said meeting: 1. The Causes and Prevention of Infant Mortality. 2. Railway Sanitation. (*a*) Heating and ventilation of railway passenger coaches. (*b*) Water-supply, water-closets, etc. (*c*) Carrying passengers with communicable diseases. 3. Steamship Sanitation. 4. Methods of Scientific Cooking. 5. Yellow Fever. (*a*) The unprotected avenues through which yellow fever is liable to be brought into the United States. (*b*) The sanitary requirements necessary to render a town or city proof against an epidemic of yellow fever. (*c*) The course to be taken by local health authorities upon the outbreak of yellow fever. 6. The Prevention and Restriction of Tuberculosis in Man. 7. Methods of Prevention of Diphtheria, with Results of such Methods. 8. How far should Health Authorities be Permitted to Apply Known Preventive Measures for the Control of Diphtheria. 9. Compulsory Vaccination. 10. Sanitation of Asylums, Prisons, Jails, and other Eleemosynary Institutions. Papers upon miscellaneous sanitary subjects not included in the above list will be received by the Executive Committee, subject to the requirements of the by-laws. The secretary is Dr. Irving A. Watson, of Concord, N. H.

# Society Reports.

## AMERICAN OPHTHALMOLOGICAL SOCIETY.

*Twenty-fifth Annual Meeting, held at the Pequot House, New London, Conn., July 17 and 18, 1889.*

FIRST DAY, WEDNESDAY, JULY 17TH—MORNING SESSION.

THE Society was called to order by the President, DR. WILLIAM F. NORRIS, of Philadelphia.

DR. CHARLES STEDMAN BULL, of New York, read the first paper, entitled

AN ANALYSIS OF NINETY CASES OF SIMPLE CHRONIC GLAUCOMA, WITH SPECIAL REFERENCE TO THE EFFECTS OF IRIDECTOMY UPON THE ACUITY OF VISION AND THE VISUAL FIELD.

Detailed histories of the ninety cases were presented, and the following conclusions formulated:

In endeavoring to draw some rational conclusions from the study of ninety cases, it seems wise to begin with a quotation from Priestly Smith, to whom ophthalmologists owe so much of their knowledge of the pathogeny and pathology of glaucoma.

1. In considering the expediency of an operation in chronic glaucoma, he says: "In every case of chronic glaucoma, the responsibility of advising an operation is a heavy one and should on no account be undertaken without a full explanation to the patient or his friends of the almost positive certainty of blindness on the one hand and of the uncertainties which beset the operation on the other. Having regard to the age of the patient, the impossibility of great benefit, and the possibility of a painful and accelerated progress, the prudent surgeon will only operate on the express desire of the patient to receive the only possible chance of benefit, however small it may be." Armed with the preceding precaution, it seems to be our duty to operate in cases of chronic progressive glaucoma, and the earlier the better.

2. If the disease in a given case seems to be stationary and is still in the primary stage, and if it be possible to test the vision and the visual field at short intervals, delay in operating is permissible, but a weak solution of eserine or pilocarpine should be used daily, merely as an aid in controlling the course of the disease. The examination of these patients should be at short intervals, and should invariably include tests for visual acuity and the careful examination of the visual field.

3. If the disease exists in both eyes but with useful vision in both eyes, the eye in which the disease is the more advanced should be operated on without delay; and the surgeon will be guided in his treatment of the fellow-eye by the result of the operation on the first eye.

4. To insure the best result, the incision should be made well in the sclerotic with a narrow cataract-knife or a broad lance-knife, and the entire iris, from one end of the incision to the other, should be carefully torn or excised from its insertion.

5. The most carefully performed iridectomy by skilful hands is sometimes followed by rapid loss of what sight still remains; sometimes partial, but, unfortunately, sometimes total.

6. A successful result is, in the majority of cases, more likely to follow the operation if it is performed early in the course of the disease, but the maintenance of the existing degree of vision even in these cases is not invariable.

7. As regards the question of symmetry, it is probable that in the large majority of cases, probably as much as eighty per cent., the disease is sooner or later present in both eyes, and a careful study of the cases seems to establish the fact that there can be no specific interval of time which insures the second eye against an attack.

8. If the patient is old and feeble and one eye is still free from disease for a year or more after the other eye has become affected, it may be considered prudent to avoid an operation on the affected eye, as it is probable that the unaffected eye may remain free during the remainder of the patient's life.

9. The condition of the field of vision is no constant guide either in forming a prognosis as to the progress of the disease or in deciding as to the time of operation.

10. The acuity of vision bears no constant relation to either the success or failure of the operation.

11. The anterior chamber is usually shallow, is occasionally entirely absent, but is often apparently normal in depth. The condition of the chamber gives no reliable hint as to the state of the vision or the visual field, nor any indication as to prognosis.

12. The appearance and motility of the iris appear to have some bearing upon the prognosis, though perhaps not to the extent believed by Nettleship. The latter states that in the cases in which the iris reacts rapidly to eserine the operation proves successful. This has not always been the experience of the reporter, but in the majority of the cases in which eserine caused rapid contraction of the pupil the visual acuity was fairly good and the field was not seriously limited.

13. The depth of the excavation in and the color of the optic disk seem to have no close connection with the defective vision or with the limitation of the visual field, nor do they offer any constant guide as to prognosis or to the effect of an operation upon the progress of the disease.

14. The condition of the intra-ocular tension is a very uncertain guide in deciding the time for operating. It may be normal, or increased, or even diminished. It does not even seem to bear any constant relation to the degree of visual acuity or to the state of the visual field. The steady maintenance of the increased tension, however, without any diminution, almost invariably indicates the necessity for an immediate operation, and this necessity is especially indicated if the tension is continually on the increase.

15. The health and age of the patient exert a decided influence upon the effect of the operation. Any marked evidence of senility is distinctly unfavorable to operation.

DISCUSSION.

DR. H. KNAPP, of New York: During the past nineteen years I have operated on six hundred and seventy cases of glaucoma, two hundred and twenty-six of which were cases of chronic glaucoma. I think that the prognosis may be a little more favorable than has been indicated by Dr. Bull. I have had four cases in which malignant disease followed operation for chronic glaucoma. I do not agree with the author as to the advisability of the continued use of pilocarpine or eserine in those chronic cases where operation seems doubtful. I advise its use when there are recurrent symptoms. In prognosis I am guided a great deal by the condition of the iris. My operations have been done with the lance-shaped knife. I consider it of great importance to carefully reduce the edges of the coloboma, not only by external pressure but also by the use of the blunt probe. I am also careful not to make the operation too peripheric. Peripheric wounds are more liable to cystoid scars.

DR. EMIL GRUENING, of New York, read a paper entitled

IRIDECTOMY IN GLAUCOMA.

The speaker classified the different forms of glaucoma under the following heads: 1, Acute inflammatory; 2, chronic inflammatory without visible degenerative changes in the iris; 3, chronic inflammatory glaucoma with visible degenerative changes in the iris; 4, simple glaucoma; 5, intermittent glaucoma; and described cases illustrative of these different varieties.

DISCUSSION.

DR. S. O. RICHEY, of Washington: I do not believe simple chronic glaucoma to be entirely a local affection. I think that it is a local expression of a cause to be looked for in the nervous system. I have used eserine with satis-

faction in the early stages, but I support it by galvanism applied to the cervical ganglia. In some cases this will enable us to avoid operation.

Dr. Samuel Theobald, of Baltimore: I have met with one case in which an attack of pronounced acute glaucoma was cut short by the use of eserine.

Dr. C. S. Bull, of New York: Eserine is frequently used in too strong solution. A solution of half a grain to the ounce may cause iritis after a single instillation. I never use a stronger solution than this. I often use one as weak as one-tenth of a grain to the ounce.

Dr. B. Alexander Randall, of Philadelphia: I can confirm the remarks in regard to the value of weak solutions. In one case of severe absolute glaucoma a solution of one-eighth of a grain to the ounce was entirely successful in relieving the pain. It has been used steadily for three years with no recurrence of the severe symptoms, and without the intervention of any inflammatory trouble.

Dr. S. D. Risley, of Philadelphia: In experimenting with weak solutions of eserine I have found that a distinct effect was experienced from a solution as weak as one-thirtieth of a grain to the ounce. If this was applied three times a day, it would in two days cause distinct browache. I have seen benefit from weak solutions where stronger solutions failed to give relief.

Dr. Henry D. Noyes, of New York: One point to which my attention was called many years ago is that in certain instances of evident glaucoma, with a large amount of refractive error, it has seemed that the aggravation of the glaucomatous disease has been dependent upon the accommodative strain. In operating I have gradually withdrawn from the extremely peripheral place of incision. I prefer to come closer to the border of the cornea than some do. This involves less risk and is easier of performance.

Dr. Samuel Theobald, of Baltimore: My experience tends to convince me that astigmatism, and particularly astigmatism against the rule, is frequently the cause of glaucoma.

Dr. Arthur Mathewson, of Brooklyn: In one case of glaucoma in which iridectomy had been done without averting the progress of the disease, a large injection of strychnia caused a decided improvement of vision, which continued. I have used it in other cases with good effect.

Dr. Emil Gruening, of New York, read a paper entitled

THE USE OF THE CURETTE IN ANTERIOR TRACHOMA.

The speaker, after referring to the various measures proposed for the relief of this condition, described an operation which he had employed in eleven eyes during the past two years. A six per cent. solution of cocaine was first instilled. The surface of the cornea and the vessels present were then scraped away with a gouge-shaped instrument, and the vessels followed well on to the conjunctiva. The eye is then washed with boric-acid solution, and warm compresses applied for four or five days. In three cases new vessels formed, and the operation was repeated. The ultimate result in all the cases was highly satisfactory. In old and protracted pannus this operation may be recommended for its directness, simplicity, and efficacy.

DISCUSSION.

Dr. S. B. St. John, of Hartford: I have used this operation in one case with the highly gratifying result of increasing the vision from $\frac{4}{200}$ to $\frac{16}{200}$. This has since still further improved.

Dr. H. F. Hansell, of Philadelphia, read a paper on

CORNEAL ABSCESS,

describing its symptoms and referring to the differential diagnosis between it and ulcer. He protested against the use of cocaine in abscess or other inflammatory conditions of the cornea. A few drops of a strong solution will often destroy the epithelium. Instillation of eserine, alternating atropine, was recommended. Operative interference should be limited to evacuation of the pus.

Dr. Charles J. Kipp, of Newark, read a paper entitled

FURTHER OBSERVATIONS ON MALARIAL KERATITIS.

The author had called attention to this condition in a paper read before the Society in 1880. He had seen one hundred and twenty cases of the disease. In all there had been paroxysms of malarial fever, and in ninety per cent. the corneal inflammation followed a few days after a paroxysm. In twenty-five per cent. the patients had suffered from similar trouble in previous attacks of malaria. The inflammation of the cornea occurred in the form of serpiginous ulceration, with narrow prolongations. The trouble began as a line of small grayish elevations, which soon broke down, forming a furrow of ulceration. In mild cases the duration is two or three weeks, while in severe cases it may last several months. There is a marked tendency to recurrence in subsequent attacks of malarial fever. In a few cases he had seen a similar affection in non-malarial individuals. The treatment consists in remedies directed to the general condition, and, in mild cases, with warm fomentation. In severe cases a one or two per cent. solution of nitrate of silver, applied directly to the furrows after the use of cocaine, answers well. In some very severe cases the actual cautery was employed. This arrested the progress of the disease and stopped the pain, provided the malarial trouble had previously been cured.

DISCUSSION.

Dr. Henry D. Noyes, of New York: During the past fifteen or twenty years I have met with cases of superficial keratitis due to malaria. It is rare to find the deeper tissues invaded. I am led to suspect a malarial origin in cases where there is exaggerated tenderness of the supra-orbital nerve and distinct anæsthesia of the surface of the cornea. The form of ulcerative keratitis which has been described I regard as of mycotic origin and have cured it by scraping thoroughly the lines of infiltration.

Dr. T. Y. Sutphen, of Newark: I have seen cases similar to those described by Dr. Kipp in patients suffering with malaria, and where there has been no distinct chill; the individuals have resided in malarious districts.

Dr. John Green, of St. Louis: I have seen many cases in which malarial fever was followed by superficial keratitis, or keratitis modified by neglect or improper treatment. I have not met with the form described by Dr. Kipp.

Dr. Emil Gruening, of New York: I have seen this form of ulcerative keratitis but I have associated it with the teeth. These patients have had tartar on the teeth, and have been in the habit of moistening the lids with saliva. I think, therefore, that the source of infection is in the mouth.

Dr. Samuel Theobald, of Baltimore: I have also seen for many years this keratitis associated with malarial trouble. These cases do not always show ulceration of the cornea. I have, in a general way, regarded this condition as analogous to herpes zoster. I have once or twice seen iritis associated with the keratitis following malaria. In one case of malaria I have seen this keratitis with herpes zoster of the temple.

Dr. J. A. Lippincott, of Pittsburg, read a paper entitled

IRRIGATION OF THE ANTERIOR CHAMBER.

This procedure is useful for the removal of débris in cataract-extraction and of clotted or liquid blood. In order to accomplish this successfully it is necessary to have an apparatus which can be readily made and kept aseptic; which will always be ready for use; which can be easily handled and the movement controlled with one hand; whose ejecting force is capable of being easily regulated; and which is free from the liability of forcing air-

bubbles into the anterior chamber. As fulfilling these requirements, he exhibited an apparatus consisting of a small metal receptacle with which was connected a rubber tube ending in a metal nozzle, the flow of liquid being controlled by a short piston in a rubber handle through which the rubber tube passed. The ejecting force can be varied by elevating or lowering the receptecal.

Dr. E. Gruening, of New York, exhibited a small flask devised by Von Graefe for the same purpose.

Dr. David Webster, of New York, exhibited two specimens of "sword-fish's eyes."

Dr. Henry D. Noyes, of New York, exhibited a "spectacle-frame" in which the nose-piece of the eye-glass was combined with the ordinary spectacle-frame.

Dr. Henry D. Noyes, of New York, read a paper entitled

ENUCLEATION OF THE EYE IN PAN-OPHTHALMITIS.

There have been reported by various observers thirty or forty deaths following enucleation, almost all from meningitis. About one-half of the fatal cases have occurred after enucleation during acute suppurative pan-ophthalmitis. At the New York Eye and Ear Infirmary there have been no deaths from this cause, when no additional operation in the orbit, such as the removal of tumors, etc., has been done. The number of enucleations, from 1868 to 1838, was 1,164; the number of evisceration, 17. Pan-ophthalmitis existed in fourteen per cent. of the cases. It seems fair to conclude that while a small risk to life is incurred by enucleation of the eye, the supposed increased risk by the existence of suppurative pan-ophthalmitis is not so far justified by the facts as to bar its performance in this condition.

Adjourned.

---

Afternoon Session.

Dr. H. Knapp, of New York, read a paper entitled

THE TREATMENT OF CARIES AND NECROSIS OF THE ORBIT.

The upper wall of the orbit is the most frequent seat of disease, and here its consequences are most dangerous. In every case of caries and necrosis of the orbit the condition of the neighboring cavities, and especially the nose, should be carefully investigated. Foci of suppuration should be freely opened, the cavity thoroughly cleansed, and drainage established. This can be well accomplished by small silver tubes provided with flanges. Rough bone should be scraped away with a sharp spoon. Necrosed portions of bone should be removed as soon as they become loose, or when they can be detached without injury to adjacent tissues. The eyeball should be protected, and, if there is insufficient closure of the lids, a plastic operation should not be postponed until the cornea becomes ulcerated from exposure.

Dr. H. W. Williams, of Boston, read a paper entitled

MULTIPLE CYSTS OF THE IRIS OCCURRING IN BOTH EYES.

The subject was a girl, nine years of age. In the right eye there was a projection resembling a large cyst, extending from the upper margin of the pupil. A similar growth projected from the temporal border. At the inner part there were two small pedunculated growths. All were of the color of the iris. In the left eye, two somewhat oval cysts filled the pupillary space. Through the square opening left in each pupil there was a little oblique vision.

Dr. T. Y. Sutphen, of Newark, read a paper entitled

SARCOMA OF THE OPTIC NERVE.

The patient was ten years of age; the tumor involved the left orbit and was of two years' duration. It was of a mushroom-shape and sprang from the optic nerve. Its size was six by five and a quarter inches and two inches thick. It was readily removed with curved scissors. As much as possible of the nerve was removed.

Dr. George C. Harlan, of Philadelphia, read a paper entitled

EXTENSIVE VASCULAR GROWTH IN THE VITREOUS.

The patient, a woman fifty years of age, presented herself, November 29, 1888, on account of disturbance of vision. Examination of the right eye showed the fundus to be slightly hazy, with small dull white spots about the macula, the remains of old hemorrhages, but no recent exudation. The disk was obscured by a delicate net-work of vessels. Otherwise there was no opacity. There was no stroma. Up to March 2, 1889, there had been several retinal hemorrhages, but there had been no change in the vascular membrane.. Vision had been reduced to $\frac{1}{10}$.

Dr. O. F. Wadsworth, of Boston, read a paper entitled

EXTRACTION FROM THE VITREOUS OF PIECES OF STEEL BY THE MAGNET.

The author described two cases in which the piece of steel was removed by passing an electro-magnet into the vitreous through an opening in the sclera. In the second case the operation was followed some weeks later by a separation of the retina, beginning at a point opposite that at which the puncture was made.

Dr. J. O. Tansley, of New York, read a paper en titled

CORNEAL TRANSPLANTATION.

The speaker reported a case in which he had done this operation for opacity of the cornea. At the first operation the opacity was not removed to its full depth, and although the cornea cleared to a certain extent, the result was not satisfactory. The operation was therefore repeated, but without any improvement in vision. In both operations there was primary union of the graft, and in neither was there any inflammatory reaction.

DISCUSSION.

Dr. L. Webster Fox, of Philadelphia: I have performed the same operation in a case of opacity of the cornea when the patient could just distinguish light from darkness. The graft healed readily without inflammatory reaction, and the patient obtained useful vision and could almost count fingers.

Dr. Charles A. Oliver, of Philadelphia, read a paper entitled

AN ANALYSIS OF SOME OF THE OCULAR SYMPTOMS OBSERVED IN SO-CALLED GENERAL PARESIS.

These observations were made on twenty well-marked cases of general paralysis of the insane. The study was limited to subjects in the so-called second stage of the disease, where the psychical symptoms had become of such a character as to necessitate control, and where motor and sensory derangement had become more or less manifest. Care was taken that each subject was seemingly free from any extraneous general disease or local disorder, and the entire study was limited to the male sex, so as to escape any conflicting and complicating changes that might appear in connection with the many diseases peculiar to the female sex. Thirty observations were made, resulting in the following summary:

1. The sensory changes herein described, which have been limited to unequal optic-nerve degeneration, decrease of retinal circulation, with subnormal direct and eccentric vision for both form and color, distinctly show lowered sensory response.

2. The motor symptoms, consisting in unequal and feeble movement of the irides, causing inequality and irregularity of pupillary areas, the peculiar form of ataxic nystagmus, the slight loss of ciliary tone, all express want of proper muscle-action—true paresis.

3. The peculiarly local conditions shown in the fundus, such as the pigment massings, the crescents of absorption, the disturbed and granular condition of the

choroid, etc., all indicate wear and tear of an abused and iritated organ.

4. Therefore these observations upon the ocular apparatus, which were most probably made during the second stage of the disease known as general paralysis of the insane, show not only local changes, but distinctly demonstrate that the series of sensory motor disturbances found are but the peripheral expression of one of the many indices of gradual loss of neural strength and power in this disease.

Dr. George C. Harlan, of Philadelphia, reported a case of "Hysterical Blindness," of ten years' duration, in a male, twenty-two years of age.

Dr. Samuel B. St. John, of Hartford, described a case of "Hemianopsia, with Peculiar Cerebral Symptoms."

Dr. B. Alexander Randall read a paper on "Simple Tests of the Ocular Muscle."

Dr. T. Y. Sutphen, of Newark, N. J., read a paper entitled

### A CASE OF DOUBLE PURULENT CHOROIDITIS RESULTING FROM MENINGITIS.

February 23, 1887, I was called in consultation to see G. W. B——, a robust farmer, thirty-nine years of age. He had always been healthy, with the exception of an occasional "bilious headache." Never had had any specific trouble. The history was that on February 9th he came in at noon, perspiring very freely; that evening he suffered with intense headache. The next morning he was apparently well, but at breakfast had a violent chill, with aching of the whole body. This was followed by high fever. Leaving the breakfast-table was the last that the man remembered for three months. From this time the patient rolled and tossed in bed, without decided delirium, but being in a stupid condition and easily restrained. Questions were answered only after frequent repetition, and the replies ran into complete incoherence. On the third day of the illness the body became quite rigid, with the head thrown backward. On the fourth day the left hand and forearm became swollen and the right eye inflamed. The left eye became inflamed on the tenth day. Later the left foot became swollen. The swelling of the hand and foot lasted about a week and then subsided. The fever then became less violent and the general condition improved, but the mental sluggishness remained. There was no paralysis, no convulsion, no vomiting. At the end of the third week he had a slight chill, and another after he was out of bed.

At present the man is apparently in good health. He has lost none of his functions and the mind is perfectly clear. When first seen by the writer the eyes were in the following condition: No swelling of the lids; moderate pericorneal injection; cornea clear; anterior chamber normal in depth; irides slightly discolored; pupils moderately dilated, with a yellowish reflex from the anterior portion of the vitreous; there was no perception of light, no tenderness on pressure, but a marked lessening of the tension of the globe. Three days later the anterior chamber in each eye was obliterated by pressure from behind the lens; the eyeballs being harder than normal. One week later the anterior chamber was again restored and tension had again fallen much below the normal. From that time there was progressive atrophy of both eyes, until now there is left only the greatly shrunken globes, with, of course, absolute blindness.

In this case there must have been an extension of the intracranial inflammation along the sheath of the nerves and not a forcing of the products of inflammation forward, as sufficient pressure within the cranium to produce this must evidently have become apparent by more or less paralysis.

The case is reported simply as a clinical contribution to this somewhat rare and obscure trouble, which is certain to be met with in the course of practice.

Adjourned.

## Second Day, Thursday, July 18th—Morning Session.

Dr. C. S. Bull, of New York, read a paper entitled

### CONTRIBUTIONS TO THE SUBJECT OF TUMORS OF THE ORBIT AND NEIGHBORING CAVITIES.

Case I.—Was an adenoma.sarcoma of the lachrymal gland. It was operated on two years ago. There has been no return.

Case II.—Was one of abscess of the ethmoid cells, frontal sinus, and orbit in a male, aged forty-six. It was opened, washed out, and drained. There was perfect healing.

Case III.—Tumor of the maxillary antrum, nasal fossa, ethmoid cells, orbit, and cranial cavity. The eye was enucleated and the maxillary antrum cleaned out. A large opening was found through the orbit into the anterior fossa of the skull, and through this the tumor extended. The evening following the operation the patient became comatose, and died the next morning.

### DISCUSSION.

Dr. H. Knapp, of New York: The report of thess cases shows the necessity of early operation in all casee of tumors of the orbit or near the orbit.

Dr. B. A. Reeve, of Canada: In a number of these cases of empyema of the frontal sinus I have found hypertrophy of the middle turbinated bone. This is a point of importance in etiology and prophylaxis.

Dr. C. S. Bull, of New York, read a paper entitled

### CASE OF DOUBLE CHOKED DISK DUE TO INTRACRANIAL TUMOR, WITH AUTOPSY.

The patient, a young married woman, twenty-three years of age, was seen, June 30, 1888. In February, 1888, had miscarriage, and was quite ill for a couple of weeks. There was dull headache at vertex. This became more severe. During April there were occasional attacks of diplopia. During May there was failing vision. When examined, $V = \frac{18}{20}$ in each eye. Accommodation was normal. There was no peripheral limitation of the field of vision, either for form or color. There was an irregular negative scotoma for all colors. There was marked exudative neuro-retinitis, with hemorrhages in both eyes. Urine proved normal on examination. The only symptoms of intracranial disease were the lesions of the optic nerve and the headache at the vertex. The diagnosis was intracranial tumor at the base of the brain. Vision rapidly failed, and by September 25th there was no perception of light. The mental faculties gradually became impaired. Right hemianæsthesia came on. The patient died May 5, 1889. Autopsy showed a tumor involving the corpora quadrigemina and extending to the anterior crura of the cerebellum. The growth appeared to be a glio-sarcoma.

Dr. O. F. Wadsworth, of Boston, reported a case of "Torticollis," cured by tenotomy of the external rectus.

Dr. Myles Standish, of Boston, read a paper entitled

### PARTIAL TENOTOMIES IN CASES OF NEURASTHENIA, WITH INSUFFICIENCY OF THE OCULAR MUSCLES.

The author reported five cases in which he had performed this operation on account of constant headache, inability to use the eyes, and neurasthenic symptoms. In all but one there was marked and prompt relief of the local and general symptoms by the operation. Cases requiring operation are comparatively rare.

Dr. David Coggin, of Salem, read a paper entitled

### NOTES ON SOME VAGARIES OF ACCOMMODATION.

One case was of hypermetropic astigmatism passing into myopia. A case of recurrent spasm of accommodation was also reported. The third case was one of temporary anomaly of sight, occurring daily. In the morning could see well, but in afternoon could not recognize objects across the street. Double vision also occurred. The disturbance is gradually disappearing.

Dr. E. E. Holt, of Portland, read a paper entitled

EFFECT UPON THE ACCOMMODATION OF A PATIENT'S EYE CAUSED BY LOOKING INTO THE MIRROR SET OBLIQUELY IN THE ROOM DURING OPHTHALMOSCOPIC EXAMINATION.

Directing the patient to look with one eye into a mirror set obliquely while the other was examined with the ophthalmoscope, an element of ease was found in making the examination and of comfort and steadiness on the part of the patient never experienced before. The eye fatigues quickly in looking at a single object. Looking into the oblique mirror gives the impression of gazing into the distance. A notable change in the pupil will be observed when the patient is directed to look at an object at the distance of the mirror, and when he is directed to look at objects reflected from it.

Dr. O. F. Wadsworth, of Boston, read a paper entitled

PARALYSIS OF THE SPHINCTER IRIDIS.

A case was reported of paralysis of the sphincter iridis, without affection of the accommodation, lasting several months and following the instillation of homatropine in both eyes.

DISCUSSION.

Dr. Samuel Theobald, of Baltimore: In all such cases it is important to exclude malingering. It would be possible for the patient, by the use of a weak solution, to keep up the mydriasis without affecting the accommodation.

Dr. Samuel D. Risley, of Philadelphia: Another practical explanation of such cases is the use of a pipette previously used for a solution of a mydriatic, for a solution which contains no mydriatic.

Dr. John Green, of St. Louis, presented a series of geometrical constructions illustrating certain cases of "oblique pencils refracted at cylindrical and spherical surfaces."

Dr. John Green also read a paper on "Some of the Stereoscopic Alterations evoked by Unequal Glasses placed before the Two Eyes."

Dr. Samuel Theobald, of Baltimore, read a paper entitled

THE EMPLOYMENT OF OLEATE OF VERATRIA TO FACILITATE THE DETERMINATION OF ERRORS OF REFRACTION.

A mydriatic affords valuable aid in myopia and in hypermetropia, but in astigmatism its use is not so satisfactory. In astigmatism he had found great help from the use of a ten per cent. oleate of veratria to the temple and forehead once a day for three or four days. This seems to exert a quieting effect upon the ciliary muscle, and especially of the radiating fibres, and lessens the tendency to asymmetrical accommodation. The following rule was formulated in regard to the correction of astigmatism: When the astigmatism is according to the rule, we need correct only that which is readily made manifest. On the other hand, in astigmatism against the rule, we are warranted in correcting fully every part of the defect which can be rendered manifest.

Dr. E. E. Holt, of Portland, read a paper entitled

THE INEFFICIENCY OF HYDROBROMATE OF HOMATROPINE IN CONTROLLING THE ACCOMMODATION FOR THE PURPOSE OF FITTING GLASSES.

The experience of the writer was that this drug could not be relied upon. He reported one case in which the latent hypermetropia revealed by a three per cent. solution of hydrobromate of homatropine was just one-half of that revealed by a one per cent. solution of atropia.

DISCUSSION.

Dr. Edward Jackson, of Philadelphia: I have found homatropine entirely satisfactory when used properly. The instillations must be repeated at short intervals, five or ten minutes, and three or four instillations practised. The effect rapidly passes off and the examination must be made within one or two hours. I have followed the use of homatropine by another mydriatic without alteration in the result.

Dr. E. Jackson, then read a paper entitled

AMETROPIA AS DETERMINED UNDER COMPLETE MYDRIASIS.

He had examined four thousand eyes under complete paralysis, and presented the following table of his results. These were compared with results obtained by another observer without mydriasis.

| | With mydriasis. Per cent. | Without mydriasis. Per cent. |
|---|---|---|
| Compound hyperopic astigmatism.. | 40 | 9½ |
| Compound myopic astigmatism.... | 9 | 11 |
| Simple hyperopic astigmatism..... | 6 | 16½ |
| Simple myopic astigmatism..... | 2 | 24 |
| Mixed astigmatism..... | 6½ | 2 |
| Hyperopia..... ..... | 31 | 10 |
| Myopia ..... ..... | 4 | 9½ |
| Emmetropia ..... | 1½ | 17½ |

Dr. Jackson also presented a paper on "Accuracy in the Prescription of Prisms."

Dr. U. S. Dennett, of New York, read a paper in which he suggested a "New Unit of Angular Measurement for Prismatic Glasses."

Dr. George C. Harlan, of Philadelphia, exhibited "Periscopic Cylindrical and Sphero-cylindrical Lenses."

Dr. W. F. Mittendorf, of New York, read a paper entitled

A CASE OF AMBLYOPIA DUE TO CHLORAL HYDRATE.

The object was to put on record a case of toxic amblyopia due to chloral hydrate. The patient had for six months been in the habit of taking forty to sixty grains of the drug at night to induce sleep. Suspension of the drug relieved the amblyopia.

---

Executive Session.

OFFICERS FOR ENSUING YEAR.

*President*—Dr. Hasket Derby, Boston; *Vice-President*—Dr. George C. Harlan, Philadelphia; *Secretary and Treasurer*—Dr. Samuel B. St. John, Hartford; *Corresponding Secretary*—Dr. J. S. Prout, Brooklyn; *Delegate to the Ex. Com. of the Congress of American Physicians and Surgeons*—Dr. John Green, St. Louis; *Alternate*—Dr. D. B. St. John Roosa, New York.

The following were elected to membership: Dr. Carl Koller, New York; Dr. R. A. Reeve, Toronto, Canada; Dr. David Harrower, Jr., Worcester, Mass.; and Dr. George E. de Schweinitz, Philadelphia.

The Society then adjourned, to meet at the Hotel Kaaterskill, N. Y., the third Wednesday of July, 1890.

---

## AMERICAN OTOLOGICAL SOCIETY.

*Twenty-second Annual Meeting, held at the Pequot House, New London, Conn., July 16, 1889.*

The Society was called to order by the President, Dr. J. S. Prout, of Brooklyn.

Dr. B. Alexander Randall, of Philadelphia, read the first paper, entitled

INFLAMMATION OF THE TYMPANIC ATTIC, AND PERFORATION IN SHRAPNELL'S MEMBRANE.

The author reported twenty cases, fifteen of which had been seen in the past six months, and urged that the condition was not a rarity. It often coexists with one or more perforations of the other parts of the drum head. If sought and recognized early, it is a less tedious and serious matter than these attic inflammations are generally considered to be. He cited some one hundred and twenty cases, reported by several observers among ten thousand patients, and, while he had seen a still larger

proportion, accepted this as the average. Passing over the treatment as having been already thoroughly discussed, he turned to the question of causation, and cited the views of Walb, that infection from without, through the "foramen Ravinii" was the starting-point. Contesting this view as to any colotomatous opening in the flaccid membrane as wholly negatived by modern embryologists, he urged that the individual variations in the septum in the attic predisposed some cases to localized inflammation, and led to perforation at this point; and that these cases, neglected or recurrent, formed the group from which the usual obstinate cases were derived. He therefore advocated scrupulous search in all cases for disease in this locality, as promising to nip in the bud what might later become disease notoriously difficult to control. The paper was illustrated by drawings and photographs of specimens.

DISCUSSION.

DR. S. D. RISLEY, of Philadelphia: I have frequently seen perforations elsewhere associated with perforation in Shrapnell's membrane. The presence of perforations in other parts of the drum-membrane does not exclude its presence in Shrapnell's membrane.

DR. J. O. TANSLEY, of New York: I have never met with perforation of that part of the drum to which the doctor refers, associated with perforation in other parts of the drum. A singular thing is that we so rarely get the perforation whistle.

DR. S. O. RICHEY, of Washington: I do not think that perforations of Shrapnell's membrane are so common as has been stated. My experience with the absence of perforation whistle corresponds with that of others. I have had cases in which perforations in other parts of the drum healed, but the perforation in Shrapnell's membrane persisted. In treating these cases, besides using measures through the external auditory meatus, I have employed injections through the catheter, consisting of nitrate of silver, one part; boric acid, ten parts; glycerine, twenty parts; and water, five hundred parts.

DR. GORHAM BACON, of New York: I have not observed this condition so frequently as Dr. Randall. It is often difficult to see these perforations. In treatment I have generally used Blake's intra-tympanic syringe. By persistent syringing and the use of astringents cicatrization is often produced. These cases are, however, very tedious.

DR. J. A. ANDREWS, of New York: In treating these cases in which there is purulent inflammation of the attic, with a large hole in Shrapnell's membrane, after injecting the cavity I suck out the fluid by means of this instrument, consisting of a delicate metal tube with a curved extremity, to which is attached a rubber tube. I use simply a boric-acid solution. After sucking out the fluid I dry it with cotton wrapped on a probe. I then blow in a fine cloud of boric acid.

DR. HERMAN KNAPP, of New York: There is a capital difference between perforations in the upper and those of the lower part of the drum-membrane. Those in the lower part may close in a few days, while in the upper part they may continue for months or years. I think this is due to difference in anatomical structure. The lower portion is a specific tissue with little association with periosteum, while the upper part is a duplicature of periosteum and skin. When the latter part is affected the process extends to the periosteum, leading to caries and necrosis of the bone.

DR. F. M. WILSON, of Bridgeport, Conn., read a paper entitled

THREE DEATHS FOLLOWING SUPPURATIVE OTITIS, WITH TWO AUTOPSIES.

Cases in which death follows a first attack are so rare that it was thought of value to report these cases. The first patient was forty years old, who for two weeks before coming under observation had had pain in both ears. February 27, 1888, the pain in the left ear became very intense. March 1st, he became partially unconscious and remained so, with occasional convulsive movements, until March 6th, when he died. The mastoid was drilled half an inch, but no pus found. No autopsy was made.

The second case, a male, aged twenty-three years, was attacked with subacute otitits. March 11th, symptoms of meningitis appeared, with high temperature, and he died March 27th. At the autopsy one-third of the base of the cerebrum was involved in the purulent process, which extended up under the frontal convolutions. There was about half an ounce of turbid fluid between the dura mater and inner meninges. There was pus in the labyrinth and in the tympanic cavity.

The third case was that of a boy, aged ten years, who was attacked with suppurative otitis September 5th, and died about ten days later. At the autopsy the meninges were found normal, but an abscess containing two drachms of fluid was found in the cerebellum.

Dr. Wilson also presented

A MASTOID DRILL,

provided with a guard which could be set at any desired point, regulating the distance to which the drill entered. The edges of the drill are sharp, so that the opening can be enlarged horizontally to any desired extent.

DISCUSSION.

DR. GORHAM BACON, of New York: It seems to me that in these cases where we do not find any collections of pus in the mastoid cells we are justified in investigating the condition of the brain.

DR. J. O. TANSLEY, of New York: I have had several of these cases, and have without success sought for some means by which we could differentiate between those cases in which there was meningitis and those in which there was abscess. In one case Dr. Seguin made a diagnosis of abscess, based upon conjugate deviation of the eyes. Subsequent autopsy showed the correctness of this diagnosis. In another case I suspected abscess. Dr. Weir opened the mastoid, but found no pus. We also explored the cerebrum, and two days later the cerebellum, but found no pus; the patient died of suppurative meningitis.

DR. S. D. RISLEY, of Philadelphia: It seems to me that in the differential diagnosis attention to the temperature in connection with symptoms of pressure is of great importance. In meningitis the temperature from the outset will be higher than in abscess, and the symptoms of pressure come on later.

DR. J. A. ANDREWS, of New York: In the past year I have made a number of autopsies in cases of brain abscess. Brain abscess may continue for a considerable time without any very positive symptoms, but where there is meningitis or phlebitis, especially phlebitis, there is usually a sudden rise of temperature, with chills

DR. OREN D. POMEROY, of New York: In a case of brain abscess, secondary to tympanic disease, the only marked symptom was a sudden rise of temperature, sometimes going up in half an hour from normal to 107° F. Intelligence was unaffected until the last. The man gradually improved, but died suddenly. The autopsy showed a large abscess of the brain covering the petrous portion of the temporal bone.

DR. ARTHUR MATHEWSON, of Brooklyn: It is often difficult to make a diagnosis between abscess and meningitis; and, in fact, many are mixed cases. In meningitis the pain is more marked than in abscess. In meningitis there is more likely to be optic neuritis, while in brain abscess I have noted a peculiar dark appearance about the retinal veins.

DR. SAMUEL THEOBALD, of Baltimore: The treatment of the preliminary stage of these cases is important. It seems to me that a great deal might be done to prevent the occurrence of the conditions referred to. I have

found benefit from local applications, especially atropia and cocaine, and morphia and cocaine. If the bowels were constipated I should use a calomel cathartic. If there should be symptoms of cerebral implication I should administer mercury in some form to secure its constitutional effect.

Dr. E. Fridenberg, of New York: During the past eighteen months I have made autopsies in two patients dead from cerebral abscess. In one case suppuration had lasted a year, but there had been no symptoms until a week before death, except irritability of temper. There was some odor, but very slight discharge from the ear. A week before death the patient developed pain in the ear, slight tenderness over the mastoid, followed by fever and symptoms of brain-pressure. A small abscess was found in the temporo sphenoidal lobe. The roof of the tympanum was carious, and the meninges strongly adherent.

In the second case the patient had had suppuration for years. Two months before death headache occurred, which was relieved by treatment. It recurred, with fever. There was some pain on pressure over the mastoid process. The symptoms again disappeared under treatment. Three weeks later he returned with similar symptoms. The next morning vomiting occurred, and that evening he died. An abscess containing two ounces of pus was found in the temporo-sphenoidal lobe.

Dr. T. Y. Sutphen, of Newark: These cases of brain trouble almost invariably follow the arrest of the flow of pus. We should look upon these cases as instances of local trouble and should treat the middle ear by fomentations, and perhaps by poultices, to bring about free discharge of pus.

Dr. R. A. Reeve, of Toronto, Canada: In one case of death following acute suppurative otitis there was the most profuse purulent discharge that I have ever seen, and it continued from beginning to end.

Dr. B. Alexander Randall, of Philadelphia: A case of cerebral abscess occurred in my practice last year in a boy, the subject of scrofulous disease of the elbow and other joints. I found both ears discharging, caries of the auditory meatus on both sides. On the left all the mastoid tissues were involved. Under treatment the right side rapidly improved, and on the left side there was also improvement. The case was then transferred to my surgical colleague. Six weeks later the ears were still in good condition, but the patient was gradually failing from the constitutional trouble. An hour before death there was suddenly a discharge of at least two ounces of fetid pus from the ear. There was no meningitis, but a large abscess cavity was found in the sphenotemporal lobe, one-half inch from the tympanum, and connected with it by a sinus.

In cases where it is thought justifiable to perform exploratory trephining of the brain, an admirable and safe point is one and one-fourth inch behind, and an equal distance above, the upper posterior margin of the osseous meatus. This avoids the major blood-vessels, and it would be possible to reach the cerebellum through it.

Dr. F. E. Holt, of Portland, Me., reported a case of

COMPLETE CLOSURE OF BOTH EXTERNAL AUDITORY CANALS BY BONE

in a patient having good hearing power, with a previous history of chronic suppurative otitis media.

T. M——, aged eighteen years, was seen in April, 1889, for an affection of the eye. It was incidentally learned that he had had abscesses in both ears when seven years old, and the ears discharged more or less for six years, but stopped entirely five years since. Examination showed the canals of both ears of about half the usual length, and occupied by a continuation of the skin of the meatus, with no appearance of the membrana tympani. There was complete closure of the canal by what appeared to be bone by all the tests employed.

The hearing power for the voice was good. The stop-watch was heard only when close to the ear, the tuning-fork was heard about ninety seconds, both by bone and aerial conduction. König's rod of thirty thousand vibrations per second was heard by both ears. He heard less distinctly when both ears were closed by pressure on each tragus. Shutting the mouth and closing the nostrils did not seem to affect the hearing power much, if at all. Cases with closure of one meatus with the skin of the canal continuous over the obstruction have been observed, but the hearing power is very defective. Cases in which there is a small opening between the exostosis and the walls of the meatus are not uncommon.

Dr. Samuel Theobald, of Baltimore: Four or five years ago I reported a case very similar to the one described, the newly formed membrane was, however, nearer the orifice. The hearing power was good.

Dr. B. Alexander Randall, of Philadelphia: I have had one case in which one ear was obstructed by a bony mass. There was no evidence of exostosis. The hearing was, however, defective.

Dr. E. E. Holt, of Portland, Me., also reported a case of

OTITIS MEDIA CATARRHALIS ACUTA, ACCOMPANIED WITH FACIAL PARALYSIS AND IMPAIRMENT OF ACCOMMODATION OF THE EYE OF THE AFFECTED SIDE.

Judging from statistics one would be led to believe that paralysis of the facial nerve in connection with acute catarrhal inflammation of the middle ear was not a common complication. In many cases the pain having been slight and having passed off, and the paralysis having come on, the patient's attention is directed to this and he seeks advice for the latter affection, and the cause of the paralysis is recorded as "a cold" or "rheumatic."

F. I.——, aged twenty-four years; seen May 19, 1889. Seven days before took cold, and right ear began to pain that night. This pain continued three days, when it subsided, and on the fourth day he was unable to use his lips properly. Examination showed all the characteristics of facial paralysis. Testing the eyes there was found paralysis of accommodation of the right eye. This the author knew to be a fact because he had previously had the patient under his care and recorded the test of his eyes, and also by the fact that since the improvement of the paralysis of the face the paralysis of accommodation has disappeared.

Dr. S. O. Richey, of Washington, D. C., read a paper entitled

THE PHYSIOLOGY OF THE INTRO-TYMPANIC MUSCLES.

The paper was the elaboration of a suggestion made by the writer in the discussion of a paper read by him at the Congress of American Physicians and Surgeons in 1888.

If the membranum tympanum in purpose protects the aural tissues lying interior to it, these muscles, being appendages to the membrane, are designed to assist the purposes of the membrane, which they do in part, by protecting it from injury by the impact upon it of sound impulses violent enough to rupture an inflexible membrane firmly attached and having such a plane as to expose it to the fullest force of the concussions. The membrani tympani fulfils one of these conditions; it is firmly attached. He quotes Toynbee and Henle as having many years ago expressed a somewhat similar view as to the action of the tympanic muscles, and states that he can find no reference to this subject by later writers. The shape and other peculiarities of the auditory meatus, the elasticity and capacity for motion of the drum-membrane and its oblique position with relation to the meatus, the co-ordination between the palatal and the intra-tympanic muscles, converting the tympanic cavity into an air-cushion, all indicate a similar purpose on the part of nature to guard the membrani tympani immediately and the labyrinth mediably from violence.

EVENING SESSION.

DR. GORHAM BACON, of New York, exhibited photographs of the ear.

CYSTS OF THE AURICLE.

Of late a number of cases of so-called cysts of the auricle have been reported. Not one of these, however, seems to represent a genuine cystic tumor, such as is found in other parts of the body. They all were situated on the anterior surface of the pinna and were of rapid development. They either were the results of traumatism and contained a sanguinolent fluid, or they developed without known cause. Mild inflammatory symptoms were present in all. The development within two or three weeks, in almost all cases, distinguishes them clearly from the slow and absolutely non-inflammatory development of true cystic tumors. All got well either by spontaneous absorption or by incision. The speaker had seen at least half a dozen of these cyst-like sub-perichondrial swellings of the auricle. He considered them to be mild cases of perichondritis, for these mild cases of circumscribed perichondritis may, instead of getting well, remain in this condition for a time and then develop into the full picture of a diffuse perichondritis. He reported such a case.

DR. KNAPP also described a case of genuine cyst of the auricle occurring in a girl nineteen years of age. The growth was double the size of a large filbert, distinctly cystic, and had developed without known cause and without any inflammatory symptoms. The cyst was removed by operation, without rupture, and was exhibited. These tumors are not frequent in the auricle, but they cannot be so rare as we might infer from otological literature.

DR. WILLIAM H. CARMALT, of New Haven, reported a case of

EPITHELIOMA OF THE MIDDLE EAR.

The patient, a robust man, aged forty-seven, was first seen in June, 1888, on account of a suppurating ear (left), which had existed forty-two years and had followed measles. The ear had given him no inconvenience, with the exception of the discharge, until a few weeks before he came under observation. He then began to have pain in and around the ear, and the discharge was exceedingly offensive. The canal was blocked by a ragged but firm excrescence, very sensitive to touch. There was slight tenderness, but no swelling or pitting over the mastoid. The pain radiated through the side of the head and interfered with sleeping. At the second visit the left side of the face was completely paralyzed. The case was regarded as one of epithelioma of the skin of the canal. The patient was seen by another gentleman, who thought the trouble might be a carious antrum. An attempt was therefore made to open the antrum, but the bone around it was so sclerosed that the cavity was practically obliterated. There was nothing of the nature of an abscess in the mastoid. The incision was then prolonged through the soft parts, and into the external auditory canals. What polypoid could be reached was removed, and a drainage-tube inserted. The mass removed proved to be carcinomatous. In the course of a few weeks the ear again became blocked up, and the skin became involved. With the object of alleviating some of the distressing accompaniments of the condition, another attempt was made to clear it out. By chiselling away the bone posteriorly, free access to the ear-cavity was obtained, and the bone scraped apparently clean. No auditory apparatus was seen, simply a mass of carcinomatous tissue. The cavity was washed with a solution of resorcin, and for a time the wound did well, but subsequently the disease reappeared. The discharges became again offensive, and the patient exhausted, and he finally bled to death without the condition being detected, probably from erosion of the lateral sinus. No autopsy was permitted.

DR. B. ALEXANDER RANDALL, of Philadelphia, exhibited a series of photographs, and made some remarks on the use of photographs and of the lantern in teaching otology.

Dr. Randall also reported five cases of

SUPERNUMERARY AURICLE,

four of the right ear, one of the left ear.

A PEA FOR NINETEEN YEARS IN THE AUDITORY CANAL.

DR. T. Y. SUTPHEN, of Newark, exhibited a mummified pea which he had removed from the auditory canal where it had lain for nineteen years. The patient had been deaf in that ear since childhood. He heard the watch at one inch. After removal of the foreign body the hearing was almost normal.

DR. B. ALEXANDER RANDALL made some remarks upon the anatomy of the drum-membrane.

DR. HUNTINGTON RICHARDS, of New York, sent a paper entitled

TWO NOTEWORTHY CASES OF TRAUMATIC RUPTURE OF THE MEMBRANI TYMPANI.

CASE I.—Seen May 7th. A woman, aged thirty, two days before had received a box on the left ear. The symptoms were vertigo, tinnitus, and marked deafness. There had been no bleeding or other discharge. There were some evidences of pre-existing tympanic catarrh, in that the drum-membrane was somewhat depressed and moderately atrophic. Save for pronounced congestion of the manubrial vessels, and a narrow red line along the border of the opening, it was not congested. The exposed inner wall of the tympanum was likewise pallid, secreting only sufficient mucus to give its surface a glistening appearance. The patient was directed to let the ear alone, and a small, loose cotton obturator was placed in the auditory meatus.

CASE II.—A woman, aged twenty-three, came under observation May 22d. There was no discharge nor bleeding. There was no congestion of the membrane or of the tympanic wall. The patient had complained of aural symptoms for several weeks. On May 21st she consulted a physician, who introduced a cotton-covered probe. This made her so dizzy that she had to lie down immediately, and within two hours she discovered that she was very deaf.

The treatment was negative, and up to May 31st no change had occurred. The edges of the opening were then stimulated with nitrate of silver solution, and a small quantity of boric acid was insufflated. Examination made a few days later showed that the opening had healed, with the exception of a small part. The patient then passed from observation.

---

EXECUTIVE SESSION.

OFFICERS FOR ENSUING YEAR.

*President*—Dr. Oren D. Pomeroy, New York; *Vice-President*—Dr. Gorham Bacon, New York; *Secretary and Treasurer*—Dr. J. J. B. Vermyne, New Bedford, Mass.; *Member of Executive Committee of Congress of American Physicians and Surgeons*—Dr. W. H. Carmalt, New Haven; *Alternate*—Dr. F. B. Loring, Washington, D. C.; *Committee on Membership*—Drs. Arthur Mathewson, Samuel Theobald, and S. D. Risley; *Committee on Publication*—Drs. J. J. B. Vermyne, C. J. Blake, and J. Orne Green.

A committee consisting of Drs. S. C. Ayres and William W. Seely was appointed to prepare a minute on the death of Honorary Member Dr. E. Williams, of Cincinnati.

The following were elected to membership: Dr. Harlan P. Allen, Columbus, O.; Dr. Ralph W. Seiss, Philadelphia, Pa.; Dr. David Harrower, Jr., Worcester, Mass.; Dr. Robert Barclay, St. Louis, Mo.; Dr. Neil P. Hepburn, New York, N. Y.

The Society then adjourned.

# Correspondence.

## OBSERVATIONS AT THE CLINIC OF DR. APOSTOLI IN PARIS.

To the Editor of The Medical Record.

Sir: For about three months during the past winter I was a constant visitor at the clinic of Dr. Apostoli, for the purpose of observing his method of treating fibroid tumors of the uterus, and noting the results.

Certainly no improvement in medicine has of late years attracted more widespread attention, if we may judge by the frequent references to it in the medical journals, the reports of societies, and the brochures which appear in various parts of the world.

The clinic is so easy of access, and strangers are so courteously received here, and given so many privileges, that there are always quite a number present, generally representing several nationalities, some just beginning their professional life, others men of distinguished reputation.

They have the opportunity of making examinations, following the cases as long as they choose, consulting the records, and drawing their own conclusions.

Every observation is dictated by Apostoli in their presence and hearing, and is recorded by a clinical assistant.

An enormous number of observations have been collected in this way embodying a mass of information, the scientific value of which can be properly estimated only by those who have watched the painstaking, conscientious care lavished on the work.

The technique of the method has been described in detail many times, most favorable results reported by independent observers in widely separated countries, and objections, theoretical and practical, fairly answered; yet many have not been able to decide upon the question of its freedom from danger, the amount of pain caused, or its efficacy.

At least it is beginning to be realized that no royal road to science has been discovered, and that a little knowledge of gynecology and a little knowledge of electricity will only lead the experimenter out of the beaten track to land him in a quagmire.

In the hands of the originator, the method produces results which compare favorably with anything done in the field of practical medicine, for if we can believe the evidence of our senses and the statements of patients, by it hemorrhages are controlled, pain due to congestion and inflammation relieved, as well as symptoms due to pressure upon neighboring organs, while the general health is restored and the patients return to active life.

In some instances it is not an extravagant statement, that the size of the tumor has been sufficiently reduced to permit child-bearing, when otherwise it would have been difficult or dangerous.

An observer, who follows the cases for a few months only, may be deceived as to the diminution in size of these tumors, and can only judge of the permanency of the results from cases which occasionally report after a long interval of time has elapsed, but he can hardly be deceived about the other symptoms mentioned above.

The amount of pain which the patient must endure has been variously estimated by different writers, being even considered by some a serious objection to the method—which is a mistake; that is, if it be properly understood and applied.

In different patients, and in the same patient at different times, tolerance or supportability varies greatly, but the rule is not to apply a current of greater intensity than the patient is able and willing to bear without urging. This limit is generally reached, but in some cases the full force of the battery causes scarcely any discomfort.

The period during which there is suffering is a portion only of the five minutes allotted to the séance, as some time is consumed in gradually increasing the strength of the current.

The patient is required, absolutely, to repose an hour after the application, during which she suffers rather from a sense of nervous fatigue than from actual pain.

However, it is during this period that some do have pains due to uterine colic, but they are seldom severe, except in cases of complete intolerance, when vomiting also supervenes. This was observed in two patients only, and had no serious results.

One, on the contrary, terminated most happily, the result being a suppression of a hemorrhage which had occurred daily for nine months. When the patient returned to the clinic she was scarcely recognizable for the improvement which had taken place. In this case only thirty milliampères were given on three occasions, for less than five minutes.

It is rare for a patient not to be able to walk to an omnibus and ride home without inconvenience, when the hour of repose is terminated.

No accidents have been witnessed at the clinic beyond the breaking of a wire or some derangement of the battery, by which a painful shock was produced—accidents which are avoidable, and consequently ought not to happen.

To avoid the possibility of septic infection from cauterization of the endometrium, or from the slight wound inflicted by the galvano-puncture, antiseptic precautions are taken in all cases.

The application is preceded by an injection of dilute creoline, which is continued twice daily by the patient. Where galvano-punctures are made iodoform gauze is applied, but in spite of it, or on account of the negligence of the patient, ulcers have resulted occasionally, which, however, were not of a character or appearance to cause uneasiness.

Many of the patients have been more or less incapacitated for work by abdominal pain and soreness, much increased by standing or walking, cæcydynia and cystitis, as well as by painful or prolonged menstruation or hemorrhages.

It is remarkable with what promptitude their condition is sufficiently ameliorated to enable them to resume work by which they gain a livelihood.

When hemorrhages have been suppressed, the gain in general health, weight, and color is easily accounted for, as the blood making processes continue in activity; but in non-hemorrhagic cases the same thing occurs, as for example in the case of a married woman who, after fourteen applications, went up in weight from 114 to 130 pounds, with proportional improvement in general health and spirits.

When menstruation has continued regular, it is not interfered with by the treatment, which is begun immediately after one epoch and continued to the next.

After the treatment is suspended, the improvement is more fully realized, because the remaining abdominal soreness continues to diminish, and the denutritive changes which have begun in the tumor continue to go on indefinitely.

There now takes place a deposit of fat in the abdominal walls over the seat of the tumor, and the tumor itself shows a tendency to become lobulated; if subperitoneal it becomes even pedunculated to an extent which brings it to the notice of the patient herself, who in one instance declared that it had taken the shape of a gourd with a crooked neck.

That great changes take place in the tumor in consequence of the treatment, is shown in cases where the sound cannot be introduced at all from the position into which the cervix has been crowded.

Galvano-punctures are here resorted to, and after a while there is a marked tendency of the parts to assume a normal position, and the sound is now introduced without difficulty.

The same thing is noticed in cases where the patient

has to be placed in the genu-pectoral position for the first few applications, after which the sound can be introduced with the patient in the dorsal position.

It is difficult to estimate correctly the diminution which a fibroid tumor has undergone, for the uterus rises high in the abdomen after repose, and sinks into the pelvis after standing. The apparent size varies greatly with the condition of the uterus as regards congestion, for if this condition be relieved, the acute symptoms subside and the tumor seems much smaller.

This lobulization, which is so evident upon palpation, indicates, especially as it goes on increasing for a long time, nutritive changes which encourage one to hope that the improvement will be permanent.

When the tumor is subperitoneal another termination is sometimes observed (as with the treatment by ergot); the mass is expelled into the uterine cavity or forms a polypus. Eight cases of this kind have been reported by Dr. La Torre, of Rome.

This is a fortunate termination, but as mere size bears no relation to the amount of mischief caused, we may be satisfied if in other cases the symptoms disappear and there is no fear for the future.

It has been asked how the electric current can produce denutrition of the tumor and increased nutrition elsewhere.

The question assumes the existence of a specific denutritive action, which it is not necessary to do, for all the phenomena can be explained upon principles already established by Onimus and others, who have shown the beneficial influence of the continuous current upon congestions, its stimulant effect upon the absorbents, and that it promotes normal nutrition.

If we analyze the symptoms, they are bound to be largely due to congestion and nervous irritation brought about by an intolerance of the organ for the lesion, conditions which are relieved long before the tumor itself could be much influenced.

The congested uterine tissues offer less resistance to the current than the tumor, hence they are the first to be influenced by it.

The subsequent changes in the tumor may be traced to the maintenance of a normal circulation, and the stimulation of the absorbent and muscular systems of the parts. A diseased endometrium often accompanies the tumor, and is a potent factor in causing congestion. The cauterization effected by the inter-uterine pole doubtless contributes to a favorable result by curing this condition of the endometrium.

It is probable that in other situations, where a lesion is badly tolerated, the accompanying symptoms can be relieved by the application of the continuous current—for example, a localized tuberculous deposit in the lungs.

The writer has no doubt that skilful physicians are able to do much for the relief of cases of fibroid tumors with other means; nevertheless, he is firmly convinced of the safety and efficacy of Apostoli's method, and would advise it under all circumstances.

More especially, he would insist that in the light of the information we possess, no patient should be subjected to a formidable operation until this method has been tried and found wanting. HOWARD SMITH, M.D.

PARIS, June 6, 1889.

---

ACCUMULATION OF BROMIDE OF POTASSIUM IN THE BRAIN.—M. Doyon reports the case of a boy who died of an intercurrent disease after from one to two drachms of bromide daily for a year. Analysis showed the presence of thirty grains of bromide in the brain and twelve grains in the liver.

PILOCARPINE IN HYSTERIA.—Dr. Vieira de Andrade, writing in *O Brazil-Medico*, of May 8, 1889, reports a case of aggravated hysterical convulsions, in a child aged twelve, in which a complete cure was obtained within a few days by the administration of pilocarpine.

# New Instruments.

## AN EASILY CLEANED POCKET-CASE.

BY S. OSCAR MEYERS, M.D.,

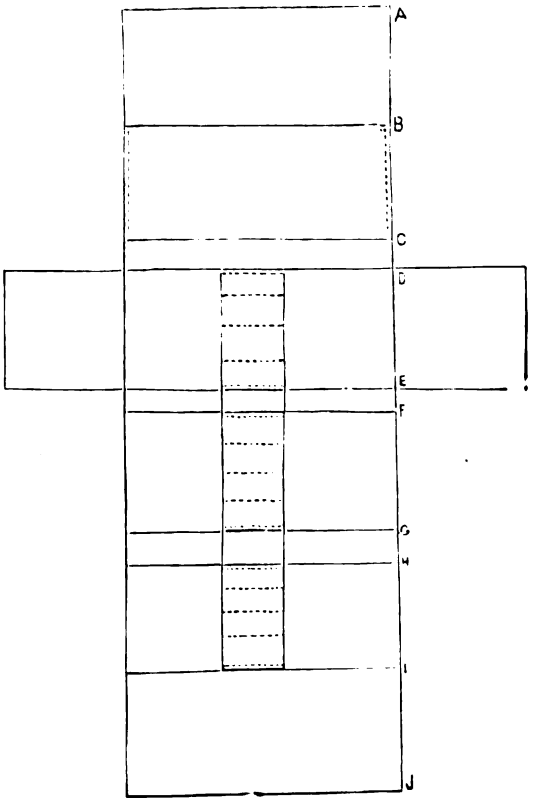
MOUNT VERNON, N. Y.

FOR the benefit of Dr. Bradshaw and others, who dislike to carry a filthy, poison-saturated surgical pocket-case, I offer the following suggestions:

Beauty must be sacrificed for utility and safety. The silver-clasped sealskin case, with its crimson silk, or "violet velvet lining with the lamplight gloating o'er," may be a thing of beauty, but after a few weeks' use it must necessarily become saturated with septic germs. Its material and make-up prevent cleansing and disinfecting.

For a simple, cheap, aseptic pocket-case, cut chamois-skin like the diagram, fifteen inches long, five inches wide, with two side-flaps, two and a quarter inches long. Fold the section A B on B C, two and a quarter inches, and stitch the two ends, thus forming a pocket for needles, silk, etc.

The sections D E, F G, H I, are each two and a quarter inches wide, and will hold four instruments each. The dotted lines show where a piece of tape, one inch wide, is stitched to form loops for the instruments. The spaces C D, E F, G H, allow for folding, and are each half an inch wide. When closed, J I folds on I H, to prevent chafing, then on G F, then E D; the side-flaps fold over the ends, and the needle-pocket over all. Two



rubber bands slipped over the ends keep it closed. Like any other case that is constantly carried in the pocket, this one will soon become more or less saturated with perspiration and effete matter from the body and clothing. To prevent this, it should be enclosed in a little bag made of sheet rubber. The superiority of this case consists in the fact that it can easily be washed and disinfected. The needle-pocket can be turned inside out; the whole case can be immersed in a solution of acid. carbolicum, acid. boracicum, or hydrar. bichloridi without injury, and when dried will be thoroughly clean and aseptic. Lastly, its cost is so little that the doctor can afford a new one every time he collects a bill.

## Army News.

*Official List of Changes in the Stations and Duties of Officers serving in the Meaical Department, United States Army, from July 14 to July 20, 1889.*

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. Ordered to Illinois National Guard, near Springfield, Ill., during remaining portion of Encampment. Par. 1, S. O. 159, A. G. O., July 12, 1889.

BALL, E. R., Lieutenant and Assistant Surgeon. Leave of absence for fifteen days granted. Par. 3, S. O. 87, Department of the Missouri, July 9, 1889.

BURTON, H. G., Captain and Assistant Surgeon. By direction of the Secretary of War the extension of leave of absence, on Surgeon's certificate of disability, granted in S. O. 22, January 26, 1889, is further extended two months on account of sickness. Par. 1, S. O. 162, A. G. O., July 16, 1889.

IVES, F. J., Assistant Surgeon, now at Fort Lyon, Cal., will proceed to Camp near Oklahoma City, I. T., and report to the commanding officer for duty, relieving Captain W. C. Gorgas, Assistant Surgeon, who, when so relieved, is authorized to avail himself of the leave of absence granted him in Par. 2, S. O. 84 c. s., Department of the Missouri. Par. 1, S. O. 87, Department of the Missouri, July 9, 1889.

GARDNER, WILLIAM H., Major and Surgeon. By direction of the Secretary of War, detailed to attend the Encampment of the National Guard of the District of Columbia, at Fort Washington, Md., from July 22 to 29, 1889, for the purpose of giving instructions to the medical officers and hospital corps in their respective duties. Par. 1, S. O. 164, A. G. O., July 18, 1889.

STEINMETZ, WILLIAM R., Captain and Assistant Surgeon, now at Baltimore, Md., on leave of absence on account of disability, by direction of the Secretary of War, will report in person to the commanding officer of the Watertown Arsenal, Mass., for duty at that station, relieving Lieutenant-Colonel James C. McKee, Surgeon. Par. 3, S. O. 166, A. G. O., July 20, 1889.

MCKEE, Lieutenant-Colonel. On being relieved at the Watertown Arsenal, will repair to Philadelphia, Pa., and assume the duties of attending surgeon and examiner of recruits in that city. Par. 3, S. O. 166, A. G. O., July 20, 1889.

ROBINSON, SAMUEL Q., Captain and Assistant Surgeon, Fort Hamilton, N. Y. H. Leave of absence for two weeks granted. Par. 11, S. O. 165, Headquarters Division of the Atlantic, July 22, 1889.

BALL, R. R., Lieutenant and Assistant Surgeon. Leave of absence granted in S. O. 87, Department of the Missouri, July 9th, is extended five days. Par. 1, S. O. 167, A. G. O., July 22, 1889.

EWING, CHARLES B., Assistant Surgeon. Promoted, in accordance with the act of June 23, 1874, to be Assistant Surgeon with the rank of Captain, after five years' service. July 5, 1889.

BALL, ROBERT R., First Lieutenant and Assistant Surgeon. The extension of leave of absence granted in S. O. 167, July 22, 1889, is further extended ten days. Par. 23, S. O. 169, A. G. O., Washington, July 24, 1889.

By direction of the President, the State of Arkansas, embracing Little Rock Barracks, is transferred to the Department of the Missouri. General Orders No. 66, Headquarters of the Army, A. G. O., July 19, 1889.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 27, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 29 | 10 |
| Scarlet fever | 45 | 6 |
| Cerebro-spinal meningitis | 3 | 3 |
| Measles | 53 | 6 |
| Diphtheria | 97 | 27 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

GERMAN PHYSICIANS AND THE PARIS EXPOSITION.—At a meeting of a Berlin society of retired medical men, not long since, a resolution was adopted calling upon German physicians to keep away from the Medical Congress to be held in Paris this summer. The members of this society were very promptly rebuked by the *Berliner klinische Wochenschrift* for their action, and the journal urged the active members to take a part in the meetings, and to show that they did not allow political feeling to interfere with scientific progress. Some hot-headed Frenchmen were incensed when it was decided to hold the next International Congress in Berlin, but we believe they have since come to look at the matter in a calmer spirit, and it is hoped that the French representation at Berlin will be fully up to the average of that at previous congresses.

A NEW METHOD OF TREATING FRACTURED PATELLA.—At a recent meeting of the Clinical Society of London, Mr. Mayo Robson showed a patient (a young woman) on whom he had operated by a novel method to secure bony union in a case of fracture of the patella. The skin over and around the joint was cleansed and rendered aseptic and the joint then aspirated. Drawing the skin well up over the upper fragment, a long steel pin was passed through the limb from one side to the other, just above the upper border of the patella. The limb being similarly transfixed just below the patella, gentle traction on the pins brought the fragments into apposition. Antiseptic dressing was applied, and left undisturbed for three weeks; when it was removed there was no sign of irritation and the temperature had never been above normal. As the fragments seemed well united the needles were withdrawn, a plaster-of-Paris splint applied, and the patient allowed to go home. Mr. Robson observed that the only precaution necessary was to draw up the skin over the upper fragment in order to avoid undue traction upon it when the fragments were approximated. If there was much effusion in the joint it would be desirable to aspirate.

SHORT-HAND FOR MEDICAL STUDENTS.—At a recent meeting of the General Medical Council of England, Sir Dyce Duckworth proposed to include short-hand among the subjects of the preliminary examination for intending students of medicine. His motion was, however, promptly voted down. Short-hand is doubtless a very useful accomplishment, but it can hardly be regarded as a necessary prerequisite to a sound medical education.

AN OLD ANATOMICAL WORK.—It is reported that there has been discovered in the Royal Library of Berlin a "Latin Manual of Anatomy," in manuscript, which was written in the year 1304. Its author was Henri de Mondeville, surgeon to Philip the Handsome of France, and teacher of Anatomy and Surgery at Montpellier and Paris. The value of the manuscript lies in the fact that hitherto we have possessed hardly any knowledge whatever of the state of anatomy at the period in question.

### TREATMENT OF INJURIES TO THE HEAD.[1]

BY DUDLEY P. ALLEN, M.D.,

VISITING SURGEON TO LAKE SIDE HOSPITAL; VISITING SURGEON TO CHARITY HOSPITAL; CONSULTING SURGEON TO ST. ALEXIS HOSPITAL, CLEVELAND, O.

ANY surgeon familiar with injuries of the head is acquainted with the difficulties which are met in diagnosticating the exact seat of injury, and its extent. The differentiation between concussion and compression, though much discussed, has been most unsatisfactory. There is great uncertainty, too, in prognosis. Some cases of severe injury result in recovery, while in other cases of apparently slight injury death occurs speedily. There are still other cases which do well for a time, and then die suddenly and unexpectedly.

It is not the purpose of this paper to discuss cases of severe injury where there are external wounds, together with a fracture and evident depression of the skull. In these there is no doubt of the necessity of surgical interference. I shall speak rather of cases where the diagnosis is doubtful, and consider what plan is to be pursued under such conditions.

As a basis for these considerations, I will state six cases of injury which have recently come under my care. The first will be stated somewhat at length, in order to show the method pursued in treatment and operation.

On September 10, 1888, Mrs. W——, aged thirty-nine, in vigorous health, while standing in a car door was thrown violently backward, by the sudden starting of the train, and struck her head upon the metal arm of a seat. When I saw the patient for the first time, on November 2d, she could not definitely locate the point struck, but placed it at about the median border of the left parietal bone, close to its posterior margin.

Patient was helped out of the car, and walked a short distance, but soon became dizzy, and was compelled to lie down. The same night, some hours later, she aided in caring for others injured in the same wreck, and the next day took a railroad ride of several hours. During the four weeks following there was much headache, but the patient was up and about. About October 10th the pain increased, and dizziness, which had previously existed, became more marked, so that patient staggered some in walking. From this time patient remained in bed until November 2d, when she was brought to Cleveland, about eighty miles, and entered Charity Hospital under my care. At this time the pain in the head was intense, and patient said she felt as though a nail were pressing upon her brain at the point where she received the injury. This pain was so severe that she threw her head somewhat backward, and seemed to want to bore the occiput into the pillow. Had a constant sensation of falling backward; slept poorly; was greatly depressed in spirits and very nervous; had previously vomited occasionally, but not recently; but the vomiting may have been due simply to gastric disturbances.

Patient was placed upon iodide and bromide of potassium, and later bichloride of mercury was added to these, and they were continued about five weeks, but with out any noticeable change.

On November 30th a consultation was held at which Drs. H. K. Cushing, W. J. Scott, Frank Weed, B. L. Millikin, Henry S. Upson, and myself were present, and the same gentlemen met again, December 7th. Dr. Millikin made repeated examinations of the eyes, and Dr. Upson of the various nervous phenomena.

The following are extracts from their examinations:

*Dr. B. L. Millikin's Report.*—"Examination of the eyes, November 3, 1888. O. D. v=$\frac{6}{6}$; O. S. v=$\frac{6}{6}$. Movement of the eyeballs in all directions normal. Pupils normal in size and reaction. The objective field for white shows undoubtedly some peripheral narrowing in both eyes. Eyes very sensitive to light ever since the injury.

"The ophthalmoscope shows in O. D. borders of disk slightly hazy, disk and retina somewhat injected, choroidal crescent to outer side of disk, arteries slightly diminished in calibre, veins greatly distended and very tortuous all over fundus of the eye, from the borders of disk clear out to the periphery all the veins being involved. O. S. shows disk slightly injected, a little haziness of borders, broad choroidal crescent outward, arteries normal in size or a little diminished in calibre, and veins likewise greatly distended and tortuous over entire fundus.

"January 2, 1889.—Fundus of eyes has changed but little since last examination. Perhaps calibre of veins slightly diminished. No haziness of borders of disk of O. D. The pupil of O. S. is now larger than O. D., but both react readily to light and to accommodation. Vision in both eyes normal."

*Dr. Henry S. Upson's Report.*—"Examination of Mrs. W——, November 3, 1888. On palpation of head there is a tender spot just to left of median line, in the posterior part of the parietal region. There is no paralysis of eye-muscles, nor deviation of face nor tongue. Patient stands somewhat unsteadily; but there is no loss of power in either arms or legs; grip is the same on both sides; sensation is acute all over the body, as well to painful as to tactile impressions. The triceps, wrist, and knee reflexes are equal on the two sides, well marked, but not exaggerated; there is no ankle clonus. The visual memory is perfectly good; patient can read very well, can recall faces, scenes, and colors as well as before the accident; there is no hemiopia.

"November 16th.—Patient has noticed a weakness of the right side, and has had sharp pains in the right toe and foot. On examination the grip seems distinctly weaker on the right side, and the muscles of the right foot act less energetically, possibly as a result of the pain in that region. There is no change in the reflexes.

"December 6th.—Patient's condition practically unchanged. Still intense pain at point of injury, and tenderness to pressure. No paralysis nor anæsthesia. Pain in right foot better since last examination. Has had some pain in the left foot. Is still rather unsteady when she stands."

To summarize the case. It appeared that an injury to the skull had been followed by severe headaches, continued for three months, and that pain and tenderness at the point injured were intense. There was also marked dizziness. Examination of the eyes showed sensitiveness to light and very marked congestion and tortuosity of the veins, indicating perhaps increased intercranial pressure. Examination of the nervous apparatus showed no focal symptoms referable to the cerebrum, unless it were a slight weakness of the right side, which, however, was not positive. There was also pain in the fourth toe of right foot,

[1] Read before the Ohio State Medical Society, May 23, 1889.

later becoming general in ball of foot. This was so severe that patient stepped on foot with difficulty. There were neither chills nor fever accompanying sickness.

In spite of appropriate medication and surroundings, patient grew worse rather than better. On this account, and from the fact that the blow upon the head was just posterior to the leg-centre of the left side, and that this was accompanied by severe pain in the right foot, and that the marked tortuosity of the retinal vessels indicated increased intercranial pressure, it was decided by the gentlemen in council to trephine at the point of greatest tenderness and pain.

On December 13th the operation was performed in the presence of the consulting physicians and several others. On the previous day the bowels were thoroughly cleared by ol. ricini; the head was shaved and disinfected, and wrapped in a towel wet in bichloride of mercury. A hypodermic injection of morphine, one-fourth grain, was administered and the patient was etherized. A flap, three inches wide at base and four inches antero posteriorly, was made down to the periosteum. The base of the flap was toward the occiput. The periosteum was divided by a crucial incision and the bone exposed. The skull was opened by a Horsley trephine one inch and three-quarters in diameter. The trephine was made for me by Gemrig, of Philadelphia.

Since the skull was of unequal thickness and about five-sixteenths of an inch thick at one side, it became impossible to complete the operation with the trephine, since by so doing the brain would have been seriously lacerated at one side before the skull was divided at the other. It was thus necessary to divide the remaining bone with a small chisel. In doing this the inner table of the skull split off, the slivered part remaining attached to the button of bone and slanting out under the periphery of the trephined opening. Thus the button was removed with much difficulty, but this was finally accomplished without lacerating the brain or its membranes. The button of bone removed was found to be uninjured. The dura mater bulged quite markedly into the opening and fluctuated slightly. This was divided through about two-thirds of its periphery at about an eighth of an inch distance from edge of bone. The pia mater was somewhat congested at the central portion, and lifted from the surface of the brain by an increase of the clear cerebro-spinal fluid. This fluid was evacuated, neither clot nor inflammatory exudation was found, nor was there any depression of the inner table of the skull. The dura mater was then united by a continuous suture of very fine catgut; the bone, which after its removal had been kept wrapped in an antiseptic towel, and under water at a temperature of 100° F., was returned to its place, the dura mater was drawn together over it by a fine catgut suture, a drainage-tube was placed under the flap up to the opening in the skull, and the scalp was united and dressed antiseptically. The patient recovered from the anæsthetic rapidly, having endured the operation well, and soon regained consciousness. The dressings soon became quite moist with the escape of cerebro-spinal fluid. A day and a half after the operation the temperature had marked 101.3° F. and the pulse 100. Ice-bags were applied, and after this it was impossible to tell whether the moisture of the dressings was due to the escaping cerebro-spinal fluid or to the moisture from the ice-bags.

On December 17th, four days after the operation, the dressings were opened, sutures and drainage-tube removed, and the wound found in perfect condition. From this time the progress of case was most satisfactory, and on December 28th patient sat up for first time. The union of the wound was by first intention throughout, and without a single drop of discharge.

On January 6th patient walked down hospital stairs, a long and difficult flight, and on January 18th went to her home. Since that time her progress toward recovery has been continuous.

After the patient's return home the left pupil was considerably more dilated than the right. On April 18th her husband writes: "The left pupil is dilated some at times, though not near so much as a few weeks ago. Within a week past I have seen more improvement than in any three or four previous. I think the trouble in the back of the head is entirely relieved. There is still some frontal headache when she exercises too much, and the eyes are weak so she cannot read very much." I now present you the lady operated upon to examine for yourselves. She seems perfectly well.

This case is one of six that have recently come under our notice, in which severe blows upon the head had been received. In none of them was there evidence of injury to the skull externally.

Case II. I saw about five weeks after the receipt of his injury. During the last four weeks the patient had had convulsions, and latterly high fever, and was comatose. I trephined. There was no depression externally, but a small piece from the internal table of the upper margin of the left parietal bone penetrated the membrane of the brain, and in the substance of the brain was an abscess containing about two ounces of pus. The case terminated fatally about one week later, the case being well-nigh hopeless at the time of operation. The clinical evidence of the case would have dictated an operation on the third day following the accident.

Case III.—Was of a man struck upon the vertex of the cranium by a shaft, but not rendered senseless. He continued at work for about ten days. I saw the patient five weeks after receipt of injury. He was then comatose, and had impaired motion of right side. Patient died one week later. The brain was removed before I had an opportunity to examine it, but was said to show no lesions which could be seen macroscopically. I examined the skull carefully, and it appeared normal in all respects.

Case IV.—Was of a man who fell from a second-story window. Was unconscious for a few moments, after which time he walked upstairs. There was considerable nosebleed, and a fracture apparent of the nasal bones. During night of injury was delirious for a few hours, but later suffered little pain, and was about the house after nine days, and three weeks from date of injury went to work regularly. During succeeding eight weeks patient was twice delirious and unconscious, but between these attacks he worked. About ten weeks from the time of injury patient was brought to hospital, when I saw him for the first time. He was then unconscious, and had stertorous breathing. It was 11 P.M., and I operated at once, since condition admitted of no delay. Trephined frontal bone of right side just above frontal sinus. The skull was cracked vertically at this point. No depression of inner table could be found. The membranes were injected, but no collection of pus was discovered, either externally or by puncturing substance of brain deeply with a scalpel. Patient's condition did not improve, and he died thirty-six hours after operation. The autopsy showed a diffuse meningitis, with a small amount of pus under the pia mater. A small piece of bone just to the right of the crista galli was fractured and depressed outwardly.

Case V.—Was of a man injured by falling from a car about fifteen years ago, and striking on head just over right eye. Was in hospital a short time. Remained well until November, 1885, when he began to be drowsy and lose his memory. On December 8, 1886, had his first epileptiform seizure, after which he became unusually stupid. Case seemed hopeless without an operation, and on January 8th I was asked to operate, which I did at the seat of old injury. A trephine one inch in diameter was used. Nothing abnormal was found. Button of bone was not returned. Wound healed by first intention. Patient got up from operation slowly. Three months later had two convulsions. Did not walk without crutches for a year. At this time resumed trade of a watchmaker, and did his work all right, but was forgetful. Later had attacks of weakness, and two years from time

of operation patient died. At autopsy the opening made by the trephine was about half-closed by bone, and fully covered by periosteum.

The inner table of the skull was normal. Effusion into the pia mater was quite marked over whole surface of brain. At many places it was stained red. Brain substance and medulla appeared normal. The microscope showed serous and bloody effusion into the pia mater very marked, with congestion of the meninges.

CASE VI.—Was of a man who three years before, and again three months later, received severe blows on right side of head. He recovered rapidly in the first instance, going to work in a few days, and in the latter on the same day as the injury. Since this time has occasional clonic spasms which are slight. Worked most of the time until about five months ago, since which time he has been unable to do so. Recently has grown much worse. Spasms and convulsions are more frequent. Is very slow and uncertain in all motions and mental processes. Walks with great difficulty, and during last week seems to have a tendency to fall backward. A possibly slight dragging of left foot. No other distinct focal symptoms discovered, by most careful examination. Opthalmoscopic examination, by Dr. Millikin, showed marked optic neuritis of both eyes, with considerable swelling of the disks and several small hemorrhages. Pupillary reactions normal. Vision of right eye, $\frac{3}{30}$; and of left, $\frac{6}{6}$.

During the week that patient was in hospital his condition grew rapidly worse. Convulsions were more frequent and more prolonged. It became evident that anything which was done must be done at once. The history of a blow upon the right side, and the slight dragging of the left foot, determined the operation over the leg-centre on the right side. Two buttons of bone were removed by a three-quarter inch trephine, and the opening was elongated antero-posteriorly by a rongeur. The pulse at the beginning of the operation was 160, and there was considerable cyanosis. The membranes bulged strongly into opening, and were congested. The convolutions were much flattened and anæmic. The finger was carried an inch outward from the opening in the skull in all directions, but nothing abnormal could be felt. A scalpel carried one and one-half inch into the substance of the brain gave no information. The dura mater was united with great difficulty, owing to the great bulging of brain. Patient died about thirty-six hours after operation. At the autopsy a grayish mass one and one-half inch in diameter was found, four inches posterior to gabella of nose and two and one-half inches to right of median line, and just anterior to the point touched by the finger in operating. Under microscope this presented the appearance of a glioma.

It may not be unprofitable, in closing this paper, to point out certain features peculiar to each of the cases mentioned.

Case I. was reported at length to show the difficulties incident to the diagnosis of a case of head injury, and also the great care requisite for operation.

It is very remarkable, too, that a button of bone one inch and three-quarters in diameter should be removed from the skull for nearly half an hour, be replaced, and grow firmly into its place, without any unfavorable symptom of any sort. It is such results as these which decrease one's fears in operations upon the brain.

Case II. is one which might probably have been saved by an early operation. There was a convulsion on the third day following the injury, and other symptoms indicating the necessity of immediate interference. The accompanying specimen shows a crack in the external table of the skull, and the depressed spicula of bone from the internal table.

Cases III. and IV. are illustrations of the fact that apparently slight injury to the skull, not so severe as to prevent the patient's working, may after a few weeks result fatally.

The accompanying button of bone, taken from one of these cases, illustrates how the skull may be cracked, and still no depression of bone occur.

Case V. suggests that injuries may result in epilepsy. That this is true seems now to be a fact well established, as illustrated by the relief secured in certain cases of epilepsy by trephining.

Case VI. suggests that cerebral tumors may result from injury. Whether this is so or not can only be established by numerous observations. The importance of quiet after injuries to the head is very great. It is not improbable that Cases III. and IV. might have recovered had they remained quiet after being injured.

A good deal might be said about methods of operating and instruments. Of the necessity of strict antisepsis there can, I think, be no question. By no other method could one expect to remove and again replace portions of the skull, and have them grow in place successfully.

As to instruments, the large "Horsley" trephine which I show you here, one and three-quarters inch in diameter, has the advantage that it opens a large field for work, and that the single piece of bone thus removed can be replaced more easily than several smaller pieces. It is, however, a very unsatisfactory instrument to use, for several reasons. If the skull were flat and of uniform thickness, there would be little difficulty. This, unfortunately, is not the case, and as a result the trephine cuts through the skull at one point, and is liable to wound the brain before the skull is divided elsewhere. If an attempt be made to avoid this by tipping the trephine, it binds so closely in the cut that it is impossible to turn it. This might be remedied to a certain extent by making the trephine conical, and the cutting grooves on the periphery of the trephine deeper and slanting, as in the small trephine I show you here. It has been suggested to me that a trephine might be constructed, consisting of a segment of a circle, so that this might be used to cut at any portion desired.

I have operated with quite a variety of trephines, and find the conical instrument, with deeply grooved sides, by far the most convenient. Several openings can be made with this if required, and the opening enlarged to any extent desired by the rongeurs which I show you here. I have used a chisel in working on the skull, but a serious objection to it is that it is liable to splinter the inner table.

The question of diagnosis of cerebral lesions is an extremely complicated one, and it is not within the province of this paper to consider it. Though it must be impossible to determine the exact character of many injuries, much can be done by a careful observation of symptoms, together with observation of the retina, for indications of intracranial pressure, of the seat of the blow upon the skull, and the possible manifestation of focal symptoms. In these observations the surgeon may receive valuable assistance from the oculist and neurologist.

In each of the operations mentioned ether was used, and was wholly satisfactory as an anæsthetic.

In conclusion, I would insist upon the fact that injuries to the head, though apparently slight, may be of serious import, and that fatal results may be averted by prolonged quiet.

I would also state my belief that, in skilful hands and with modern methods, the dangers of operations upon the cranium have been greatly diminished, and that timely interference will save many cases of injury to the skull which have formerly been left to nature, and resulted fatally.

---

MULTIPLE BIRTHS IN NICE.—According to statistics published by Dr. Berlin in the *Nice Médical*, the proportion of twin-births in Nice to the whole number of births is 1 to 75.54, and of triple births 1 to 5,575. In France the proportion of twin-births to the whole number is 1 to 101, and of triple births 1 to about 10,000. Dublin surpasses Nice, however, the proportion for twin-births there being 1 to 57.

# THE TOXIC EFFECT OF COCAINE HYDROCHLORATE, WITH REPORT OF A CASE.

By CHARLES H. CHETWOOD, M.D.,

NEW YORK.

EXPERIMENTS testing the physiological effects of cocaine upon the lower animals have shown that different animals of the same species vary greatly in their power of resisting its toxic influence, and that the toxic symptoms produced often differ in their nature, being convulsions, sometimes tetanic, more often epileptiform, and at times paralysis, coma, and death, not preceded by convulsions. And so it will be noticed, in the use of a moderate amount, as an anæsthetic on the human subject, while in the majority of instances no ill effects may be experienced, yet occasionally we meet with cases which show a marked susceptibility to its influence, exhibited by symptoms sometimes mild, and less often violent.

It is not infrequent after the injection of a small quantity of cocaine under the skin, or local application to some mucous membrane, for a patient to become garrulous and somewhat excited, or show other mild symptoms of general excitement.

These milder symptoms are of various qualities, being sometimes different degrees of mental excitement, or, when more of a depressing nature, slowing of the circulation, general pallor, nausea, and fainting. They have no direct relation with the amount of cocaine used; they sometimes occur where the quantity is small, and in other cases where it is larger do not appear.

The case I am about to report is one which occurred during my service as House Surgeon in Bellevue Hospital, and merits some notice on account of the peculiar and rather violent symptoms produced.

The patient was about twenty-five years of age, and was afflicted with a stricture of the anterior urethra which it was deemed advisable to cut. About a drachm of a four per cent. solution was thrown into his urethra, and shortly afterward another drachm, most of the first having escaped; so that, in all, not much over one drachm remained in contact with the urethral mucous membrane. An examination by the bulbous bougies had previously been made, hence a possible dissolution in the continuity of the mucous membrane, and a consequent greater absorption, should be taken into account.

Within three minutes after the introduction of the cocaine the patient seemed to be unnaturally nervous and excited, his pupils showed marked dilatation, and the lids being retracted gave him a very wild appearance. His excitement greatly increased, he soon became unruly, so that it took several men to hold him down, against whom he fought wildly and vociferated loudly. His actions resembled what is seen in an attack of acute mania.

Outside of the maniacal symptoms the cocaine manifested its effect in another form, which was an interesting feature, and consisted in tetanic, or tonic, spasms of the muscles, as varying from epileptiform, which is more often met with as a result of cocaine.

At the onset of the attack the patient was on a table, and though he fought and resisted, it could be noticed that both arms were markedly drawn up and the muscles rigid. There was also spasm of the muscles of the thorax, which was apparent from the impaired respiratory movements. In getting upon his feet and attempting to move, he walked "stiff-legged," and the spasms became more acute when he tried to use his muscles; in fact, without assistance he would have fallen down. During the attack the pulse was rather slow, and there was a general pallor of the external surface.

He was given a hypodermic of whiskey and eight minims of Magendie, and in a few minutes' time became more quiet, and submitted to being put to bed. Within a quarter of an hour the whole attack had passed off, the pupils became normal, the spasms had ceased, and all that remained was a feeling of dizziness, and a vague recollection of having made a disturbance, without any vivid remembrance of what had occurred.

Other cases, partaking of one or the other of the characters of this one, have undoubtedly been met. Tetanic convulsions do occur, although they are usually epileptiform. Whether one is the effect of the cocaine on the spinal cord, and the other on the cerebral cortex, I am not prepared to discuss. Professor Mosso, of Turin, in experimenting on animals, after cutting the spinal cord high up, still induced violent tetanic convulsions by the use of the drug, and it was invariably the rule, after death following the occurrence of epileptiform convulsions, to find extensive anæmia of the cortex cerebri.

Many cases of epileptic convulsions have lately been reported following the use of cocaine as an anæsthetic, and one or two have terminated fatally. *Sajous' Annual*, of this year, mentions a number of cases, notably one reported by H. C. Simes, of Philadelphia, where the convulsions were excessively violent, and resulted in death twenty minutes from the onset.

I witnessed a case in Bellevue Hospital which might have terminated fatally but for the active and immediate measures employed.[1]

Besides these cases of epilepsy, grave conditions are occasionally met, in the use of cocaine, in which convulsions do not appear. As an example of this I quote a case of almost instantaneous death, preceded by collapse and not by convulsions, and probably referable to cocaine, recorded by W. T. Belfield, of Chicago.[2] Abadie [3] gives an account of a patient who died in a somewhat similar manner, following the application of cocaine to the eye, death being preceded by coma and paralysis, and not by convulsions.

In summing up the various untoward symptoms which may follow the use of this drug, we find that we have mental excitement of different degrees, generally ushered in by headache, dizziness, and dilatation of pupils; more or less cardiac depression; it may be only slight irregularity of the pulse, but has amounted to total collapse; and dependent upon the cardiac depression cyanosis, difficult respiration, general pallor, fainting; reflex phenomena, such as nausea, vomiting, colic, evacuation of bowels; and then the more violent symptoms which occur: convulsions, epileptiform and tetanic, producing often only a transient commotion, but which have been so severe as to result fatally; and finally, paralysis, coma, and death, not preceded by convulsions.

The pupils generally become dilated after the administration of cocaine, and do not necessarily imply the onset of more alarming symptoms.

Notwithstanding the frequency of cases combining one or more of the above symptoms, which have occurred and have been reported, the progress, of late, in the use of cocaine as an anæsthetic, has been very marked, not to mention its numerous internal indications.

However, many of those who have had recourse to its use, and who have come in contact with cases which have evinced evil symptoms, are constrained to acknowledge something of the same kind of fear of this drug that a person is apt to feel toward a dog by whom they have once been bitten. Some have ceased to employ it entirely.

While it cannot be denied, from the present report of cases, that cocaine has acquired a dangerous reputation, yet it is possible that amid the enthusiasm with which it was first received, and has since been used, many lacking an adequate knowledge of its different effects, which experience alone could render, by being unwary of lesser tokens, have been unprepared to ward off the more violent and dangerous symptoms, which a resort to immediate measures might have prevented.

It is scarcely necessary to mention that the administration of the other anæsthetics in common use is not de-

[1] Case spoken of by Dr. Keyes, Sajous' Annual for 1889.
[2] Journal of the American Medical Association, 1887.
[3] Recueil d'Ophthalmologie, October, 1888.

void of risk, and they too, undoubtedly, in their early career, had their "chapter of accidents." It is only through long experience and a careful study that we are now enabled to give them fearlessly; and by having attained a knowledge of the complications which are liable to be met, are prepared to combat them when they arise; so that, at the present day, cases of disaster are comparatively rare. Their administration is entrusted to a special assistant, who continually keeps watch over the patient's general condition. Of course, as cocaine is only used locally its employment can hardly be compared to that of the general anæsthetics. But these facts are intended to suggest that a proper knowledge of its untoward effects, a careful watch for bad symptoms whenever it be used, together with future experience, are the means through which we will learn to more clearly understand this drug. If it be always used with stimulants, and such antidotes as morphia, strychnia, and nitrite of amyl near by, and someone at hand other than the operator to take alarm in case of emergency, there certainly will be less risk in its employment.

In regard to the strength of the solution to be employed, except in special cases a four or five per cent. is most commonly used where the surface to be anæsthetized is large, and where it is of small area a few drops of a ten per cent. solution.

Those who have had much experience in its use report severe symptoms following the weak, as well as the stronger, solutions in quantities relatively small. There exists, therefore, a great difference in individuals in their power of resisting its toxic influence.

A weak power of resistance may be acquired by an habitual or constant use of cocaine, and this I believe to be the explanation (if it be ascribed to cocaine) of Dr. Belfield's case, which has been mentioned, and upon whom, it will be seen, subsequent to an internal urethrotomy, two drachms of a four per cent. solution were used prior to each introduction of the sound, producing, possibly, a chronic hyperæmia of the kidneys, which eventually became overloaded; and of the case in *La Medicina Practica*, December 15, 1888 (Dr. Lettier), violent symptoms were aroused by a four per cent. solution of cocaine in the bladder, the patient being in the habit of injecting, himself, an ounce or more of a similar solution into his bladder every day; and of other cases, where there is a sudden appearance of toxic symptoms in those who have for some time previous resorted to the use of cocaine.

In order to obtain the best local anæsthetic effect of cocaine, it is well to wait ten minutes after its introduction, during which time any tendency to constitutional symptoms may be detected.

In operations where it is practicable, the application of a ligature above will retard its entrance to the general circulation, and enforce its local influence.

The value to the surgeon of such a local anæsthetic as cocaine has proved to be, can hardly be estimated; and it is to be hoped that time and experience will help us to extend its usefulness, as well as overcome its present defects.

46 East Thirtieth Street.

Where are the Allopaths?—An act has recently been passed by the Legislature of Tennessee to regulate the practice of medicine and surgery. According to this act, one of the requisites for the practitioner is the possession of a diploma from "a legally chartered allopathic, homœopathic, or eclectic medical college." The act also creates a board of medical examiners, and provides that "the three schools of medicine, viz., Allopath, Homœopath, and Eclectic shall be represented on said board." There may be some "allopaths" in Tennessee, and if there are, they are doubtless entitled to a representation; but it seems hardly fair to exclude altogether the regular practitioners of the State from the board of examiners, or not to recognize the diplomas of regular medical schools.

## A CLINICAL NOTE ON THE USE OF CREOSOTE IN PHTHISIS.[1]

By JAMES E. NEWCOMB, M.D.,
Assistant Physician Roosevelt Hospital Out-Patient Department.

My experience concerns sixteen cases treated at the above-named institution, and two in private practice. For various reasons the latter two cannot be considered as bearing on the efficacy of the treatment. Of these 16 cases, 11 presented consolidation, 2 cavities, and 3 both, *i.e.*, consolidation at one apex and a cavity at the other—advanced cases. Of the 16 there were 8 of each sex. The average age was twenty-five, the youngest thirteen and the oldest forty-six. The average duration of treatment was 78 days, the shortest 40 and the longest 141 days. The average duration of the disease, as ascertained by the symptomatic history given on application for treatment, was 28 weeks, the longest 72 and the shortest 2 weeks. In one case the patient felt perfectly well till the occasion of his taking cold, when he immediately applied for treatment and was found to have commencing consolidation at the left apex. Another patient had had lung trouble several years, and this too is not of the above number. The average is reckoned on 14 cases. In 5 cases there was a family history of phthisis. In 8 the temperature was normal; in all the others more or less pyrexia. Night-sweats were present in 11. There was a history of distinct loss of weight in 12. In 12 there was hæmoptysis. In all, if the cough was at all severe, a simple cough medicine was used of antimony, ammonium muriate, and small doses of morphine in differing combinations. Creosote was given only by the mouth. The formula I have followed was as follows:

℞. Creosote,
Tinct. capsici.....āā ʒ iij.[2]
Mucilag. acaciæ ..... ℥ ss.
Water .....ad ℥ iv.
M. S.: Dose, one teaspoonful well diluted in water after meals.

In 11 there was unconditionally no gastro-enteric disturbance from the remedy.

| | | | | | |
|---|---|---|---|---|---|
| Cough lessened in | 8, | cured in | 2, | unaffected in | 3 = 13. |
| Fever " | 4, | " " | 1, | " | 3 = 8. |
| Sweating " | 5, | " " | 1, | " | 4 = 10. |
| Weight lost | 4, | gained | 4, | " | 8 = 16. |

To summarize: seven cases were apparently not in the least improved, 7 were distinctly benefited, and 2 I regard as cured. At the time of their last examination there was not the least sign or symptom of any active process going on in the lung. They felt as well as ever. Were able to do their usual work. One had been under observation fourteen weeks, and the other twenty weeks.

In collating these cases I have decided, in every doubtful point, against rather than for creosote. I am well aware that these observations are defective as regards the influence upon the bacilli. When they were begun it was with no intention of presenting them in this public manner, and examinations of the sputa were not made. I feel conscientious, however, about the diagnosis, and I am bound to say that creosote has done more in my hands than any other remedy I have ever used. Of all the cases of phthisis I had seen, up to the time of beginning creosote, in a hospital experience of eighteen months and out patient service of four years, I had never seen but one case cured on the usual treatment of tonics, cough-mixtures, and cod-liver oil.

Concerning the *rationale* of the action of creosote, I believe that it is a direct antiseptic and disinfectant. I do not know whether it is a specific against the bacillus. I think not. I believe, however, that it is not irrational to expect that such an one may be found. I think, too, that the sclerotic change which results on the arrest of tubercular invasion is not so much the specific effect of creosote as nature's process, set up when the virulence of the poison is checked.

## CASE OF COMPOUND TRIPLE DISLOCATION OF THE LEFT ASTRAGALUS, WITH COMMINUTED FRACTURE—RECOVERY, WITH A USEFUL FOOT.

By WILLIAM A. GOTT, M.D.,

VIROQUA, WIS.

The case under the above caption presented so many interesting and, I may add, instructive features during the time it remained under my immediate supervision—a period of over three months—that I have thought it worthy of being placed on record in the columns of The Medical Record.

In order that a definite idea may be formed of its progress from first to last, it will be necessary to enter somewhat into detail. It is my purpose to do so in as concise a manner as will suffice to give a clear understanding of the main points the case presented during the time it remained under treatment.

It will suffice, for the present, to say that from the time the patient received his injury to that in which the safety of the foot was an assured fact, grave and apparently insurmountable difficulties beset the progress of the case, and so far compromised the integrity of the limb, to say nothing of the life of the patient, as to call for the consideration of the question of amputation.

Surgical authorities, without exception, agree in the opinion that dislocations and fractures of this bone, simple and compound, are not only of rare occurrence compared to other less severe injuries of the bony structures, but of great severity as well in the majority, if not in all, of the cases, and consequently of the gravest import, imperilling oftentimes the integrity of the limb, and perhaps the life of the patient also; and, no doubt, those of the profession who have been privileged to have under observation a case of the kind will confirm their statements in these particulars. Judging from my experience in the case to be described further on—the only one that has come under my observation and care during the course of a general practice of over thirty years, three years of which time were spent in the capacity of a medical officer during our late Civil War—I can truly say that, so far as difficulty and, it may be added, uncertainty of accurate diagnosis is concerned, no other class of bony injuries will bear comparison. The reason for this is obvious. As is well known, intense inflammation and enormous tumefaction invariably attend these injuries, of a more pronounced character than the same conditions met with in lesser injuries of the ankle-joint, as a severe sprain, or a fracture of both bones of the leg in that vicinity; and these same conditions, in an aggravated degree, so obscure for a while the normal contour of the joint and foot as to render a differential diagnosis a matter of difficulty, and oftentimes of impossibility. What has been the experience of eminent surgical authorities, both at home and abroad, in regard to these injuries, has likewise been the experience of surgeons of lesser note, as found recorded in the current surgical literature of the day. There is, perhaps, no class of injuries to which the human frame is liable in the pursuit of the various daily avocations of life, which the medical man is called to treat, that require the exercise of more sound judgment, acute discrimination, and prudent caution; and, certainly, no other in which he is more liable to err by reason of too hasty a diagnosis, because of the conditions already spoken of, and, moreover, in which his professional reputation in the estimation of both the patient and his sympathizing friends, especially when an opinion, which subsequent developments prove to have been erroneous, has been too hastily given, is more at stake than in the one under consideration in this paper. In the case soon to be detailed the force of some of the above statements is well shown, as will be seen, and will doubtless serve the purpose of making the medical man who may be summoned to treat an injury of this character more than usually guarded in his opinion until such time as later developments point out conclusively his line of conduct.

Case.—On the morning of June 15, 1886, I was called to visit C. B——, residing several miles in the country, twenty-two years of age, of spare, but wiry build, and a constitution somewhat impaired by reason of alcoholic excesses. Was informed that in the early evening of the previous day his team, which he was driving on the highway near his place of residence, took fright, became unmanageable, and ran away. In his efforts to control the thoroughly frightened animals he was thrown out of his wagon upon the whiffletrees in such a position as to fasten with a vice-like grip his left ankle between the evener and whiffletree on the right side, and in this position, with his body prone between the wheels, he was dragged at a high rate of speed the distance of several rods along the highway and through the dense brush into which the maddened animals finally plunged, and in which they became so entangled that their farther progress was out of the question. As soon as his team came to a stand-still his foot was released and he fell to the ground. When he had recovered from the shock of the accident he was assisted to his home by a couple of travellers who happened along at the time. After resting awhile he proceeded to make an examination of the injured part in order to "size up," as he expressed it, if possible, the nature and extent of his injury, and, having detected a "bunch" on the anterior aspect of the ankle-joint, he very naturally came to the conclusion that it had become displaced and that consequently its reduction should be attempted without delay and before the swelling, already forming rapidly, became any greater. A resolute fellow naturally, he directed his attendants to make extension and counterextension, and another to make pressure on the "bunch" alluded to; these efforts were continued for two or three minutes when "a loud snap" was heard and the bunch found to have disappeared; consequently all thought that reduction of the joint had been effected and that, so far, all was well.

After listening attentively to the above statement of the patient, I proceeded to make as thorough an examination of the part as it was possible to do without the aid of an anæsthetic, which, unfortunately, was not at hand. Sixteen hours had elapsed since the receipt of the injury. I found the lower third of the leg, the ankle, and foot enormously swollen, tense, and tender, and on the anterior aspect of the joint a strip of excoriated integument of a dull white color and mottled appearance, three inches in length and an inch in width, and which appeared to have been deprived of its vitality by reason of the undue pressure to which it had been subjected between the opposing bodies alluded to. Unable, after long-continued manipulation, to detect the usual signs of a fracture or dislocation, and owing to the excessive swelling of the parts by which the natural contour of the joint was for the most part obscured, I felt at a loss to determine the real nature of the injury—whether a luxation, fractures of one or more of the larger tarsal bones, or both combined, had been received; yet at the same time, in view of the peculiar circumstances under which the injury had taken place, together with the general appearance of the limb, its uniform and excessively swollen condition, far in excess of that usually seen in severe sprains of the same joint, I felt convinced that the ankle-joint had sustained an injury of the gravest character, the final outcome of which the future alone would disclose.

The patient, on being informed of my rather gloomy view of his case, was not disposed to accept it as conclusive; on the other hand, he strenuously insisted that his ankle-joint had been displaced, and properly replaced by the efforts of his friends. Here, then, was an instance in which physician and patient could not agree; and while the one was in a measure non-committal for the time being, by virtue of the inherent difficulties attending the case, and consequently guarded in his utterances as to prognosis—as a medical man is in duty bound to be who has any regard for his professional reputation and at the

same time takes into consideration the contingency of a suit for alleged malpractice because, perhaps, of an expressed opinion in an unguarded moment and under the stress of persistent solicitations on the part of both the patient and his sympathizing friends—the other was positive and emphatic in his opinion, ignoring probabilities as unworthy of consideration and, therefore, needless to be entertained. In his view of the matter the patient was both right and wrong, as will appear later on.

Notwithstanding the fact of the apparent difference in opinion between physician and patient, I obtained his consent to place the limb in a fracture-box for better security, improvised from such materials as happened to be within reach, and for the speedy abatement of the inflammatory action that had taken place and was still in progress to employ cold water irrigation until such time as I was able to visit him again. On the fifth day following I again visited the patient, to find him in good spirits, with little or no pain and a marked improvement in the local symptoms under the employment of the cold-water irrigations directed on the occasion of my first visit; so much so, in fact, that gentle manipulation was no longer necessary. The strip of integument previously mentioned had become gangrenous, dry, and shrivelled, while a line of demarcation had formed on all of its attached sides, along which the dead and living parts touched; beneath the central portion of this strip, but obscuring it from view, was felt what appeared to the touch a rounded, smoothly convex surface, and slightly movable from side to side under firm pressure. It now appeared evident that this was the astragalo-scaphoid articulating surface, and that the astragalus had sustained a fracture through its neck, with its fragment so displaced as to present the articulating surface just mentioned directly upward and transversely. In this view, it will be seen further on that I was grievously mistaken. In justice to myself, however, I will say that had the patient at this visit consented to a thorough examination of the ankle, as he was urged to do, involving necessarily an enlargement of the existing wound, the real nature of the injury would have been speedily disclosed and the proper operative measures instituted, without, as was the case, the long, not to say dangerous delay, before anything of a radical nature was attempted. To this, however, he stubbornly refused to give consent, for reasons already stated. At this juncture of affairs I was half-inclined to retire from the further supervision of the case, for reasons that will appear manifest to those who have been placed under similar circumstances, yet at the same time it must be confessed that I was anxious to keep it under observation on account of its rarity, comparatively speaking, as well as its peculiar nature, involving a large and important joint. At this visit I induced the patient to consent to the application of a plaster-of-Paris cast to his limb, in order to secure absolute rest to the joint.

Without entering into more extended and, perhaps, unnecessary details, it will suffice to say that during the interval in which this dressing remained *in situ*—a period of sixteen days—a rapid decline of the local symptoms took place; the tenderness and tumefaction of the parts so far subsided as to permit the patient to go about on crutches and avail himself of out-of-door exercise without much inconvenience. The patient was finally induced to submit to an operation, and for that purpose came to this place on July 5th. On that day the plaster cast was removed, preparatory to the operation on the day following. On its removal the tumefaction was found to have quite disappeared, the long, narrow wound remaining after the separation of the gangrenous integument cicatrized at either extremity, and its central portion presenting a healthy granulating surface, from the bottom of which the rounded head of the astragalo-scaphoid articulating surface protruded, and still somewhat movable from side to side.

On the morning of the sixth of the month named above, twenty-one days after the receipt of the injury, after the parts had been made aseptic and the patient placed under the influence of chloroform, the operation was made, in which I was ably assisted by Dr. A. B. Bickford, of California, temporarily on a visit to relatives, and Mr. Frank Morley, a student of medicine in my office. The original wound was enlarged at either extremity for a short distance, and by a vertical incision parallel with the flexor tendons; after which the index-finger was introduced into the wound for the purpose of exploration. I soon found that the neck of the astragalus was intact, and that the entire bone had been dislocated in such a way as to have abandoned all of the articulating surfaces to which it is applied, tibia, fibula, calcaneum, and scaphoides; in other words, its scaphoid articulating surface looked directly upward and transversely, or nearly so, its superior or trochlear surface backward, and its inferior surface forward. As far as could be determined by the exploring finger, the bone, as it lay in its abnormal position, was thought to be intact, at the same time that the finger could not be made to reach to the bottom of the cavity for want of space. The bone was still firmly held in its anomalous position by its ligamentous attachments, which required division before its extraction could be effected. After its removal, examination showed that it had sustained a comminuted fracture—its entire posterior surface having been literally ground off, so to speak, by the force applied, including, of course, the groove which transmits the tendon of the flexor longus pollicis, with nearly one-half of the posterior articular facet on its inferior surface and of the trochlear surface as well. After the removal of the bone a number of small fragments were removed with the forceps, and the débris remaining at the bottom of the deep cavity washed out with carbolized water, the wound duly drained, dusted with iodoform, and lightly dressed with antiseptic cotton, the open method of treating such a wound being deemed preferable to that in which sutures, adhesive strips, and bandages are employed, and the limb firmly secured in the bracketed wire splint represented in Ashhurst's "International Encyclopedia of Surgery," vol. iv.

Without entering into the details of the case as it progressed from day to day, it will be sufficient to say that for a few days its aspect was everything that could be desired. On the sixth day, however, a change for the worse took place. A high grade of inflammatory action of the remaining structures of the joint supervened, attended with the usual accompaniments of inflammatory action, and progressed with such rapidity and intensity that within twenty-four hours from the time of its approach the inferior half of the limb was as greatly and uniformly swollen as at the time I first saw the case; and, as may be supposed, severe constitutional symptoms added to its gravity. These symptoms continued with varying intensity for nearly three weeks before any well-marked signs of amelioration in either were observed; and, it is proper to add, so far compromised the safety of the patient as to call up for consideration the question and propriety of amputation of the limb as a last resort, as already stated. Fortunately, however, for the patient, and in spite of his oft-repeated clamorings for release from his suffering by the sacrifice of his limb, the more alarming features of the case gradually gave place to other more favorable features under the judicious use of quinine, morphia, and, especially, cold-water irrigation, for the space of nearly three weeks. From this time the case went on gradually toward ultimate recovery. After the deep wound had healed, with but a trifling amount of suppuration from first to last, as soon as the state of the parts admitted, systematic passive motion was employed at frequent intervals, and continued until flexion and extension were almost, if not quite, as good as in the sound foot—a gratifying result to both patient and physician, surely; and, I may add, altogether unexpected from the first. He was finally discharged from under my care in the latter part of September following, three and one-half months from the time his injury was received.

Before closing this paper I cannot resist the impulse to say a few words in commendation of the cold-water irrigation employed in the case. In my opinion, it proved to be the most effective weapon for good that could have been employed, and I am well convinced that by no other method could the severe local symptoms have been so successfully combated as proved to be the case in this instance. By its unremitting use for days and days the deep wound was kept clean and aseptic, the local heat and pain within endurable limits, and the tumefaction at rest; in short, as the patient expressed it, it conduced more to his comfort than all other treatment combined.

A few words in regard to the condition of the foot something over a year from the time of his discharge from under my care, before concluding. At this time he informed me that, with the exception of a slight limp, walking is attended with no difficulty, and with little or no fatigue, even when a long distance has been covered; and that, as far as he can determine, his left foot, for all practical purposes, was as good as his right.

---

## ON A VISIT TO BIRMINGHAM AND TO MR. LAWSON TAIT.[1]

By J. MILNE CHAPMAN, M.D., M.R.C.S.,

MEDICAL ATTENDANT TO THE NORTHERN INFIRMARY, INVERNESS, SCOTLAND.

As I had the advantage during February of seeing Mr. Tait at work for a fortnight, and of enjoying frequent opportunities of personal communication with him, I have thought that an account of the time so spent might be of interest to the members of our society, and might not perhaps be without profit.

In the first place I may warn those who, like myself, may be anxious to see Tait at work, that it is no very easy matter to do so, at least it does not appear to be, though I am quite sure that he will specially welcome any one coming to him from the North of Scotland, where he himself first saw ordinary medical practice. He is a Scotchman heart and soul, and delighted to talk to me of his experience while acting as *locum tenens* and assistant to Dr. Soutar of Golspie. He receives very numerous applications from practitioners anxious to see him operate, but as the bulk of his work is private, and is undertaken in ordinary sized bed-rooms, it is impossible for him to gratify them all. The story is told of one of our transatlantic cousins who, on one occasion, presented himself in Mr. Tait's consulting room about mid-day, and after greeting him and expressing his pleasure at meeting him, introduced himself and stated that he had just arrived that morning in Liverpool, was on his way to London, and had stopped on the way to see him operate. He had only an hour or two, but would like to see him do one or two sections. This, of course, is an extreme case, but the applications were so numerous, not only to see one operation, but to be allowed to see twenty, thirty, forty, or one hundred cases, that Mr. Tait felt compelled to institute a system of pupilage which is now in operation. He receives four post-graduate pupils for periods of six months at a fee of one hundred guineas. For this they are privileged to see all operations in the same way that I was, and which I shall presently describe, and also, two at a time, they attend with him when he sees his hospital outpatients on Mondays and Thursdays. This seems a heavy fee for such advantages, but there is no doubt that it is a good speculation for his pupils, and he has many more applications than he can comply with. Those who have already passed through the system and are now at work, in America and elsewhere, have succeeded in speedily establishing for themselves positions and practices which they might not so readily have obtained otherwise. America is an enormous country, and possesses numerous large cities, and, therefore, openings for such specialists as are thus trained.

On my first presenting myself to Mr. Tait on the day of my arrival in Birmingham, he took me to his secretary's room, and instructed her to send me word of when operations were to take place, and I was told there was to be one that afternoon at 2.30. At that hour I accordingly returned to the house and was shown into a small drawing-room in the hospital wing, where I was presently joined by his pupils. After waiting a little, a nurse opened the door, and we all trooped upstairs into a small, ordinary bed-room with white painted wooden floor and strips of carpet. Resting with its lower end against the window sill, was a narrow operating table with the patient already anæsthetized. Mr. Tait, in shirt sleeves and holding a small knife between his lips, was standing by the patient's side. No greetings were interchanged even by look, nor was a word spoken. One of the pupils rapidly washed his hands and took up his position opposite as assistant. This post, however, is almost purely a sinecure, as Mr. Tait does practically everything himself. The making of the abdominal incision was the work of less than sixty seconds, and what particularly struck me was the way in which he handled his knife. Never in all my experience have I seen anyone make a knife cut like he does. The instrument is a narrow-bladed short scalpel, and he lays it down so that the whole length of the blade cuts. The effect is like that of cutting butter with a good table-knife. You hardly notice any motion, but the tissues separate in front of the knife and the incision is made, clean down in many instances to the peritoneum. One or two touches at most make the wound even from end to end, and then he picks up the peritoneum in two pairs of pressure-forceps and cuts straight down between them, the assistant meanwhile holding one of the two pairs; these are then removed, he runs his knife up and down the peritoneum and the abdomen is open, actually in a shorter time than it has taken me to read this description, and with a neatness and dexterity which I fear no words of mine can fully convey. The case I speak of was one of fibroid tumor, in size about that of a four months' pregnancy. Mr. Tait rapidly enlarged the incision up and down by putting the tissues on the strain with two fingers in the abdomen and running his knife inside the abdomen edge upward, the whole wall splitting with as much apparent ease as the leaves of a book before a good paper-cutter. He inserted his hand behind the tumor and worked about for a time. As there was nothing to see of the operation at this time I turned my attention on the operator's face. It is a curious face, as those who have seen it will readily admit, long and large featured in every respect, except the mouth, which is unusually small with thin, firmly compressed lips. A heavy band of hair—which is long and black and glossy—hung down over the forehead and eye, but what then impressed me was the rigid concentrated attention expressed on every line and feature. The eyes were turned upward to the corner of the window, but were very evidently looking at nothing. Presently he said "Trocar," and a long curved one being handed to him, he took it in his right hand and pulled the point back till it was within the cannula, and slipped the instrument down in front of the left hand, which was still within the abdomen. Having settled its position, he held it secure with his fingers on the cannula shield, and having with the thumb slid the trocar forward, he pushed the instrument still deeper, and on withdrawing the trocar, there gushed out about a pint of thick offensive pus. He then said that there was the same condition on the other side and asked for the aspirator, but meanwhile continued to work away at the sac from which the pus had come, and presently brought it to the surface, a hugely dilated Fallopian tube of the right side. He tied the pedicle in the Staffordshire knot and removed it. He then went to work on the other side, but the sac burst, and he simply squeezed the pus out, fished the sac to the surface, and ligatured straight away. He then brought a

[1] Part of a paper read before the Inverness Scotland Medical Society, March, 1889.

third mass up from behind the uterus—oval, and as large as a breakfast-roll, which turned out to be a dermoid cyst of the right ovary. The pedicle of this was secured in the same way. At the time he gave this third mass not a moment's consideration, but laid it aside, proceeding to wash out the abdomen, using three large pailfuls—about the size of stable buckets—of warm water, running through an ovariotomy tube and trocar. During the process of washing out he moved the contents of the pelvis and the intestines freely about with the left hand to secure their being thoroughly cleansed. Looking at the uterus, he determined that it contained a fibroma, and impressed by the amount of mess that was about, he resolved at once to remove it. As his method of doing this is fully detailed in his writings, I shall not enter into a discussion of the process; suffice it to say that the neatness and dexterity he displayed forced the conviction on me that I was witnessing the performance of a real professor of the surgical art, and thrilled me with a sensation which a lover of music, who had never heard other than second- or third-rate performances would feel, were he suddenly to hear the strains of a Paganini.

But to complete the history of the case under consideration. It was found that an adhesion which had existed between the rectum and the tumor on the left side was persistently oozing. There was no room for ligature, and Mr. Tait first tried pressure with a sponge. As this failed to stop the oozing he rubbed the surface over with a piece of solid perchloride of iron, and as even this did not completely succeed he made a watery solution of the perchloride and applied it with a sponge. He then dried out the abdomen with sponges, inserted a drainage-tube, and stitched up the wound. The whole operation took fifty minutes, an unusually long time for Mr. Tait to take over any operation.

Here I would say a word as to a use of the drainage-tube which is but imperfectly understood, and that is its good effect in stopping bleeding from torn adhesions. Blood effused into the abdominal cavity shows little tendency to coagulate save in a very fitful and fragmentary way, probably from its admixture with peritoneal fluid. If, therefore, there is oozing from torn adhesions into a completely closed abdomen the blood does not coagulate fully, its presence sets up free secretion of peritoneal fluid, which reacts and leads to further bleeding and still more defective coagulation; while, on the other hand, if a drainage tube is employed and the pelvic cavity kept dry by frequent withdrawal of blood and serum, oozing will soon cease.

The operation in question having been completed we—that is, the pupils and myself—silently left the room and soon left the house. Next morning I got a postal card saying that there would be two operations at the Private Hospital at 9.30 A.M., and one at the Woman's Hospital, Sparkhill, at 2.30 P.M. The first was a doubtful case of distention of the gall-bladder. In less than five minutes Mr. Tait had opened the abdomen over the region of the gall-bladder, established the diagnosis of malignant disease of the transverse colon or omentum, and closed the wound. I learned afterward that the patient left the hospital in a week, none the worse. Of course, had the case turned out to be one of gall-stones she would have been relieved of her trouble there and then. In the afternoon I saw an ordinary case of removal of the uterine appendages. I shall not stop to discuss this class of cases; the one that I saw on this occasion was certainly an instance where the operation was perfectly justifiable, judging from the condition of the parts removed. When the operation began I took out my watch to time it. Having carefully looked at it I put it in my pocket and turned to the operating-table, when, to my surprise, I saw that the abdomen had been opened and Mr. Tait was fishing with two fingers of the left hand (which was all the incision would admit) for the diseased organs. On getting these between his fingers he slipped down a pair of forceps, seized them, and in this way brought them to the surface, at the same time pressing down the abdominal incision and walls with the back of his hand and holding the ovary and tube between his fingers. He then passed the ligature through the pedicle, ran the loop over the appendages, arranged the Staffordshire knot, pulled each end firmly, tied a single knot, and then fastened a pair of catch-forceps on each of the threads, wound the thread three or four times round the handle of the forceps, and seizing a pair in each hand he let go the ovary and firmly pulled the knot tight. This method of securing the knot he carried out without the slightest assistance and while he held the parts to be removed in his own hand. I describe it thus in detail in the hope that I may convey to you some idea of the marvellous dexterity of the man. The other side was similarly dealt with, and the operation was completed in ten minutes.

Mr. Tait only spoke once during that time. Just when the patient was laid on the table, the Sister who was giving the anæsthetic put out her hand to lift the arm on the table. Tait tapped her on the shoulder and said, "Attend to your own business." This is quite characteristic of the man. He has everything reduced to a perfect system, and everything goes on with just such steady regularity and apparent simplicity as do the manœuvres of a well-drilled regiment of soldiers. Trespassers, however, even be their fault as slight as the one I have just mentioned, are at once rebuked, just as the soldier would be who ventured on any irregularity during parade.

Among the other cases I saw operated on were a simple ovariotomy, which was completed in five minutes, neither sponge nor fingers having been placed within the abdominal cavity, and the incision being not more than one and three-quarters inch long; a difficult ovariotomy; removal of tubes containing pus; removal of one ovary and tube glued together and adherent to the back of the uterus and floor of the pelvis, the other ovary having been removed five years previously. In passing I may remark that Mr. Tait has ceased to remove single ovaries (except for cystic disease), as his experience is that for inflammatory mischief a second operation always becomes necessary sooner or later. I was also present at a hysterectomy and at an exploration of the kidney. In this latter case I saw illustrated the value of pressure in checking hemorrhage. The wound was of course a very deep one, the pelvis of the kidney being opened into, and the bleeding was very free, much freer than mere oozing, but, to reach the bleeding-points would have involved enlarging the incision very much. The wound was packed full with dry sponges, and these were firmly held down by the hand for two or three minutes. On taking them out the bleeding was markedly diminished but had not ceased, so the packing was repeated and again repeated, when it was found that the wound remained dry. A drainage-tube was inserted, and the stitches were tied with a running-loop knot, with long ends so that they might be undone if required. Instructions were left that should hemorrhage occur a solution of perchloride of iron was first to be injected through the drainage-tube, and that should this not succeed in checking it, the knots in the stitches were to be slipped, the clots cleaned out, sponges wrung out of perchloride of iron inserted and firmly packed in. The sponges that were used were simply wrung out of plain water.

I have since learned that all the patients I saw operated upon made prompt and good recoveries.

One thing I saw Mr. Tait do which I certainly have no intention of imitating him in. He used two of the fingers of his left hand as a sort of Sims speculum, and, kneeling by the bedside with the window facing him—the field of operation therefore completely in the dark—he freely curetted the uterus without in any way fixing it. He then inserted a short Ferguson speculum, and through this passed into the uterus a thermo-cautery. No doubt the cervix had been previously fully dilated, and probably the end in view was satisfactorily accomplished, but I hardly think the somewhat free-and-easy method I have described

will commend itself to the profession at large. Though Tait may manage to dispense with the ordinary aids of speculum, light, and vulsella, the general run of us, I think, had better continue to perform our curettings in a more orthodox fashion.

I was disappointed in not being able to see Mr. Tait perform the operation which bears his name for restoration of the sphincter and perinæum, as the written descriptions of it are not very easy to follow. I talked it over with his assistants, and they told me that he only takes five or ten minutes to do it.

It may have struck you that I have alluded to two operations which went no further than exploration, one of the liver and one of the kidney. And here I would say a word in regard to Mr. Tait's position on the subject of exploratory or confirmatory operations, for, in respect to this more than to almost any other question, he has been very greatly misrepresented, and I shall, as far as possible, make use of his own words. We have all heard him spoken of as a man who "would put his hand into a woman's abdomen with as little compunction or reflection as he would put it into his trousers pocket;" and also we have heard him quoted as saying, when in doubt as to diagnosis, "open the abdomen and find out;" or, even still more grotesquely, he has been accused of not being able to make a diagnosis in the ordinary fashion, but of opening the abdomen and taking a look in when there is a complaint of anything inside, and of doing this in as much a routine fashion as one opens the mouth and looks in where there is a complaint regarding the throat. Let me quote his own words:

"I have long since thrown the uncertainty of diagnosis, as an impediment to the adoption of proper treatment, to the winds, and when I find my patient in danger of death from conditions within the abdomen which do not seem to be clearly of a malignant character, but a correct diagnosis of which is impossible, I open the abdomen and at once make the diagnosis certain and successful treatment possible."

This was written in 1876, and further he says that he does "the same things when the conditions were such that the patient's life was a misery by reason of suffering which could not be relieved, or at least had not been relieved in any other manner. The result has been an enormous advance in abdominal surgery, obtained only after a severe struggle with the authority of the elders who asserted that the abdomen was a region into which the writs of ordinary surgical laws should not run."

As a defence of exploration I would further quote from Mr. Tait's writings: "This principle of exploration is nothing new. In fact, the way it is sometimes used, or rather abused, is almost horrible. I once saw a surgeon, who is now a baronet, remove a breast with a tumor in it, and after the whole thing was over he took the tumor in his hands and drew his knife across it and out rushed a lot of pus—'laudable pus.' He had made his exploration after the treatment had been completed. If he had explored first, his diagnosis would have been completed before his blunder had been made, and the radical operation and treatment would have been rendered wholly unnecessary. I have similarly seen a limb amputated for a sequestrum opening into the knee-joint which a preliminary exploration would have shown to have been capable of removal without amputation, and the limb would have been saved. Crowds of illustrations of this kind of practice could be given, showing in the first place that complete accuracy of diagnosis is no more possible in the breast than it is in the abdomen; that exploration is a sound principle when there is doubt, and that many ghastly blunders would be saved if the practice were extended into general surgery. Absolute accuracy of diagnosis in the abdomen is very far from being possible; only the ignorant assert that it is, and only fools wait for it."

More than any man, or, I might almost say, single-handed, Mr. Tait has established this principle of exploration in doubtful cases of abdominal disease when life is threatened. He has been the better able to do so from his extraordinary success as an operator. But what one man has done another may do, and I can quite well foresee that before long it will be considered as bad practice to allow such cases to die without operative interference as it would now be to leave a man blind from cataract without giving him the chance of again enjoying the blessings of sight, for fear that an inflammatory attack might necessitate removal of the whole eye.

Another charge that is freely made against Lawson Tait is that he does not tell the truth. The statements he had to make regarding his work in the earlier years of his practice were so startling and novel that they were not at first accepted as true. Time—the righter of all wrongs—has proved by results that the facts and theories then advanced can, and have, stood the test of experience, and though Mr. Tait's theories and deductions are not very generally accepted as correct, the impression caused by their startling enunciation still finds expression in the charge of untruthfulness I have just mentioned. Now, it is absolutely impossible for Mr. Tait to tell lies regarding his operations or his results. Of the four pupils who watch every operation, each keeps an accurate note-book for his own reference and use, in which he details everything that happens both in Mr. Tait's hospital and private work. This has gone on for years; Mr. Tait's results are published down to February 2d of this year, yet they have never been questioned by any of those who, had there been occasion and justification, could have done so successfully. Nay, I may say more, that I have met eight or ten of Mr. Tait's past pupils and not one of them doubts a word he ever said. They have seen what others have not seen. They have had personal opportunities of detecting any such tendency to perversion of the truth, but one and all they have expressed their unbounded admiration for the man and for the surgeon.

I had myself good opportunities of forming an estimate of the character of the man. We spent together from Saturday to Monday at Malvern, as guests of an old Scotch practitioner there, and many were the topics that we discussed. I do not wish to make this anything of the style of the modern society journal, so I shall not enter into the private life of the man, I shall only say that I found, as I was fully prepared to find from a perusal of his writings, that he is a man of master intellect, that the range of his knowledge is wide and far-reaching, that the accuracy of his knowledge of details is surprising, that his tastes are refined and cultivated to an extraordinary degree, and that his capacity for the enjoyment of recreation, amusement, and the good things of this world generally is unlimited. As to the type of his mind, I would say that it is essentially mathematical and scientific, and I would ask you is it not your experience that those possessed of minds of such a type are naturally and instinctively, as well as habitually and by training, rigid sticklers for the truth.

Before concluding I would briefly touch upon three outstanding departments of Mr. Tait's life-work. Already I have referred to what he has done in establishing the principle of exploration as applied to the abdomen. One outcome of his work in this direction has been his demonstration of the fact that very many of the cases where masses are felt at the sides of the uterus, and which are called peri- or para-metritis, and are treated as such, are really cases of occlusion and distention of the Fallopian tubes with fluid of various kinds, or of chronic inflammatory adhesion of tube, broad ligament, and ovary. There are also many cases in which the functional utility of the organs is completely destroyed by disease, and in which, further, the disease, such for instance as pyosalpinx, constantly threatens the life of the patient. Mr. Tait has demonstrated that cases such as these are quite amenable to surgical treatment. What suffering he has relieved and averted, what life he has saved and prolonged by these means passes my ability to conceive.

His work, too, in elucidating the natural history of uterine myomata, and in elaborating their surgical treat-

ment, is to my mind of the greatest interest and importance. His papers on these subjects at present appearing in the *Birmingham Medical Journal* will well repay careful perusal, and ought to prove an effectual antidote to the effects of the electrical mania which is at present rampant.

And, finally, there is what I consider the crowning triumph of his life, the establishment of the principle of immediate abdominal section in cases of ruptured tubal pregnancy, by his magnificent results—two deaths in forty-two cases of an accident which, without interference, is uniformly fatal.

## Clinical Department.

### NEUROTIC OR HYSTERICAL FEVER.

By CLARENCE KING, M.D.,

MACHIAS, N. Y.

MARKED elevation of temperature in hysterical individuals, unassociated with any visible structural cause to explain it, has received but little attention from medical writers, and those who have mentioned the subject have mostly done so to deny its existence. These either attribute the fever to fraud ingeniously practised by the patient or to an accompanying disease undiscovered by the physician. There are, however, in my opinion, a sufficient number of cases recorded by various observers to justify us in acknowledging this as one of the rare manifestations of the neurotic temperament. Thus Mitchell, as quoted by Mills,[1] has recorded a case of an hysterical female, thirty-eight years of age, whose temperature ranged from 95° in the morning to 100 or 100.5° F. in the evening, and whose pulse was never less than 130 per minute, even when lying quietly in bed. This patient was suffering from no pulmonary or visceral trouble, and no cause could be assigned in explanation of the elevated temperature aside from the neurotic influences. Debove, according to the same author,[2] cites a case of a female, twenty-four years of age, in whom the thermometer sometimes registered as high as 102° to 104° F., and in whom the mention of the somnambulistic state would raise the temperature from 1° to 2° F. Bressler[3] has also called attention to cases of elevated temperature lasting from a few hours to several weeks, which were associated with an accelerated pulse, vomiting, perverted appetite, and extreme sensitiveness of the abdomen. The disease usually began with sensations of chilliness, loss of appetite, constipation, furred tongue, and head ache, the temperature early reaching a high degree and remaining there, or being subject to sudden and marked variations. The pulse was usually increased in frequency. The disease was distinguished from peritonitis by the fluctuating character of the abdominal pain, absence of tympanites, ovarian tenderness, and variability of temperature.

In this connection a case occurring in my practice may be of interest to some of the readers of THE MEDICAL RECORD.

Lovina C——, female, married, aged twenty-one, mother of one child; neurotic temperament marked, inherited from father.

In June, 1888, I saw her professionally for the first time and found her in the fifth month of pregnancy, lying apparently unconscious in an hysterical attack. She had not been troubled a great deal with nausea; passed abundance of urine; bowels quite regular. Her friends told me that she had always had these "fits," but of late she had been quite free from them. I took her temperature twice and found it each time 100° F., her pulse being about 97. I could discover nothing to account for the fever. The following day she was around the house again.

Ten weeks after this I saw her again in one of her fits and found her much the same as at my former visit; temperature, 102° F.; pulse, 100. I took her temperature three times, twice under the tongue and once in the axilla, and sat where I could watch her while it was being taken. Each time the thermometer registered nearly the same. Again I could find no structural disease to explain the fever. The next day her temperature was 99.5° F., and I did not see her again, but her husband told me that after having several of these fits she "was all right again."

October 1st, I was called to attend her in her confinement. Upon my arrival I found her in the first stage of labor, again lying apparently unconscious in one of her fits, the os dilated to the size of a nickel, pains occurring about every twenty minutes and becoming more frequent and severe. Whenever she had a pain she would rouse up and groan, but after its subsidence would quickly sink into her former unconscious state. As her pains became more severe these fits were discontinued, and she was finally delivered, after a natural though somewhat slow labor, of an eight-pound male child. Imagine my surprise at my next visit, ten hours afterward, to find my patient with a temperature of 105° F., a pulse of 120, the bowels only a little sensitive to pressure, and everything else, so far as I could ascertain (and I made a thorough investigation), perfectly normal to a puerperium. The lochia was about normal in quantity and not fetid; bowels and bladder empty; no lung trouble, and absolutely nothing to explain the high temperature. She had no chills; the womb was well contracted; the breasts flaccid, and not tender or painful. For the next four days her temperature ranged between 103.5° and 105° F. She slept well, took some nourishment, but still had "fits" at irregular intervals. While I was still looking for evidences of phlebitis or other disease to explain the fever, her temperature and pulse suddenly dropped to about normal, and she made a fairly good convalescence. Her milk came the night following the day that her fever left her. Her friends told me that she had a similar complication when her other child was born, which had frightened the attending physician the same as it had me.

Three weeks after the birth of this child I saw the mother again in another of her "fits," and found her temperature 104° F.; pulse, 120. No lung trouble or disease in any organ, that I could find. This lasted two days, and suddenly dropped to normal.

Six weeks from this time I was again called to see her and again found a temperature above 104° F. and a pulse correspondingly high. All the indication of disease I could find at this time was a moderate diarrhœa. The next day her temperature and pulse were nearly normal, and her diarrhœa better. Since this time I have treated her for pneumonia, during which her temperature was only moderately elevated.

Here, then, are five observations in the same patient of high temperature with nothing to explain it. It might be urged that in each instance there was some positive disease present which I failed to detect; as, some may claim after her confinement the fever was due to puerperal infection, and in the last observation to diarrhœa. A temperature of 105° F. following childbirth is suspicious of puerperal infection, but can we base a diagnosis of infection on the fever alone? In this instance I was uneasy about my patient and called in consultation another physician, and he failed to find anything to suggest infection except the fever and pulse. Ten hours after parturition is early for infection to give rise to a temperature of 105° F., while we must admit that the excitement of childbirth would be a potent factor in producing hysteria.

In the treatment of this case the therapeutic measures employed were simple but efficient. Antifebrin was given only during the high fever following her childbirth. Hyoscyamus, valerian, bromides, tonics, etc., were prescribed in each instance, and baths, out-door exercise, and laxatives in the interim.

[2] Op. cit. [3] MEDICAL RECORD, 1888

## SCIRRHOUS CARCINOMA OF THE BLADDER, WITH VESICO-RECTAL FISTULA.[1]

By THOMAS C. KENNEDY, M.D.,
SHELBYVILLE, IND.

The case presented is one of great interest, and is generally considered rare, probably on account of mistake in diagnosis, as was first made in this case. If a post-mortem examination had not been allowed, and it was positively refused when I first broached the subject to the friends, the correctness of diagnosis would not have been questioned, and the case would have passed for simple chronic vesical catarrh.

I was called to see Mr. J. D. M——, carpenter, aged seventy-two, April 16, 1888. When I entered the room he was sitting over a vessel trying to urinate. There was considerable vesical tenesmus and he was suffering great pain. He complained that the passage of urine produced a burning in the urethra, with a feeling of weight in the perineum. He had a sharp lancinating pain in the suprapubic region and over the right kidney. There was a constant desire to empty the bladder, which he attempted to do about every fifteen minutes. He had had a chill every day about 9 A.M. He was very restless the night before I saw him, and passed a few drops of highly colored urine four or five times an hour.

I introduced a soft-rubber catheter, and drew off two ounces of residual urine. I prescribed morph. sulph. (gr. ¼), to be given every three hours until relieved; also gave pil. quin. sulph. (gr. iij.) every two hours, with directions not to disturb the patient if asleep.

I remained with the patient about one hour; at the end of that time he was resting comfortably.

April 17th. Rested very well until about midnight, having been up seven times in six hours to empty his bladder. At twelve o'clock (midnight) he took another pill of morphia, but did not rest as well after midnight as he did before. He urinated sixteen times between midnight and 6 A.M. There was less pain in passing urine than there had been. The bowels acted slightly this morning.

At 5 P.M. of same day I found the patient quite comfortable. He had a light chill that morning, but rested well all day and slept about two hours in the afternoon. He passed urine twelve times in eleven hours.

An examination of the urine was made, with the following results: Sp. gr., 1.030, highly acid; is negative as to albumen and sugar, but shows an abundance of stringy mucus. I ordered hot fomentations to be applied over the region of the bladder, and also a hot hip-bath in the evening; morphine to be given to relieve pain, if necessary. Lime-water was to be drunk, to neutralize the acidity of the urine.

From this time the patient improved rapidly, pain was diminished, and the desire to urinate decreased. By April 25th he was able to be up part of the day, and, the weather being pleasant, he was permitted to be out in the yard a few moments at a time. This improvement continued until May 8th, when he was suddenly seized with a sharp, shooting pain in the urethra and perineum. The bowels began to discharge at 4 A.M. He had very copious evacuations for several hours, when the discharges became thin and slimy.

The urine was very offensive, having a strong fecal odor. I gave opium to control diarrhœa, without any notable effect. About nine o'clock he was taken with a chill, and had rigors for several hours. He complained of an accumulation of gas in the bladder, and said it caused great pain when passing through the urethra. The escape of this gas could be heard distinctly at a distance of three feet. A vesico-rectal fistula was suspected, but this could not be confirmed by a rectal examination.

The patient continued to go from bad to worse until, upon May 13th, I began the use of "lithiated hydrangea," and discontinued all other remedies except morphia in one-eighth grain doses. He improved again until June 11th, when he walked across the street and talked to a neighbor for an hour. He felt stronger, but did not attempt to do any work. On June 26th he walked to the post office, a distance of one-half mile, and stopped at my office on his way home. He said he felt well, except that he was "troubled by the blowing, before passing urine."

On July 29th I was hurriedly summoned to see him; the messenger saying that the old man was dying. Found him in bed complaining of violent pains in the bladder. Had a severe chill, followed with fever and delirium. Temperature, 104° F.; respiration, 22; pulse, 98. With the urine were passed small particles of fæces, and also shreds of broken-down muscular tissue. He had cleaned up his shop that day, and filed a saw. While he was still at work, he was suddenly seized with a cramping pain in his bowels and had to be taken to the house. From this time he began to lose flesh, lost all appetite, and a diarrhœa commenced that baffled all efforts made to check it. All the former symptoms of pain, vesical tenesmus, frequency of urination came up with renewed vigor and could not be controlled.

On August 14th Dr. Edward F. Wells was called in consultation. Acting upon his suggestion, we washed out the bladder with a weak solution of boric acid, from which the patient received temporary benefit. The patient continued to grow weaker, became emaciated, and on August 26th lapsed into a semi-comatose condition from which he could not be aroused. On August 30th he died from exhaustion.

About ten hours after death I held a post-mortem examination, being assisted by Dr. E. F. Wells. Drs. McFadden, Green, and S. A. Kennedy were present. A large tumor was found in the apex of the bladder, which also involved the entire body down to the trigone. On the posterior wall was an ulceration of a considerable size. Almost in the centre of this ulcerated surface a fistula of large calibre was found, connecting the bladder with the rectum. Inflammatory adhesions bound the bladder to the rectum, and there were also metastatic deposits found in the rectum and intestines. I sent a portion of the tumor to Dr. E. R. Palmer, of Louisville, Ky. After having made a careful microscopic examination, he pronounced it to be a scirrhous carcinoma.

At no time during the progress of the disease was there any hæmaturia, although Stein ("A Study of Tumors of the Bladder," page 36) says that "all tumors of the bladder present, more or less, sooner or later, the triple symptoms, hæmaturia, irritable bladder, and pain."

## Progress of Medical Science.

ECZEMA IN CHILDHOOD.—In writing upon the pathology and therapy of infantile eczema Dr. Schieff says that the study of the causes of the disease, and what many are pleased to call predisposition to it, is better carried out in the infant than in the adult. The author bases his paper upon 1,017 skin cases treated in the Vienna Children's Hospital, out of which number 449 were instances of eczema. Eczema capillitii gave 230; eczema faciei, 57; eczema universale, 30, etc. The anatomical changes are given as an enlargement and hyperæmia of the vessels of the papillary body, a serous and cell exudation into this and the mucous layer. The papillæ are in consequence elongated and broadened, and so produce the nodule or papule. In greater new formation of cells in the papillæ, and more abundant effusion in the mucous layer and between it and the horny layer, by which the latter is raised up, a bulla is formed. If in such a lesion the quantity of exudation cells increases and becomes greater than the serous fluid, a pustule is formed. In more intense inflammation the corium becomes involved. When the acute eczema goes over into the chronic form we find the papule

often extremely enlarged, the vessels increased in calibre, the epidermis and corium thickened, at times pigmentation, indications of increase in connective-tissue growth, and disappearance of the panniculus adiposus. As regards etiology, it is especially noticeable that eczema appears most frequently in the first and second years of life, 136 cases in the author's table being put down for the first year and 143 for the second. There are four reasons why this is so: 1. The thinness of the epidermis. 2. The superficial disposition of the papillary body and its plexus of vessels. 3. The comparatively greater turgescence of the skin in the infant compared with the adult. 4. The habitual hypersecretion of the glands of the skin. The epidermis being thinner, there is more rapid desquamation of the horny layer, and the papillæ and their vascular net-work lie nearer the free surface and are only protected from external irritating influences by a thinner layer of horny tissue. The skin is thus much more readily affected by irritants, and by reason of the delicacy of its formation the latter much more quickly produce lesions of the tissue than is the case in the skin of adults. The glandular system of the skin being so active, and the product of the glands being so disproportionately rich, we have here one of the most fruitful sources of external injury in the irritation set up by the fatty-acid-fermentation products of the skin secretions. These and other disturbing influences do not probably in themselves dispose the child to eczema, but only influence its production in so far as they affect the nutrition, blood-supply, functions, and sensibility of the skin, or possibly in some cases exercise some especial irritant action. Although among external causes we must place in the first rank an accumulation and decomposition of the natural secretions of the skin, especially in children at the breast, still the number of sources of irritation is infinite. Among them must be mentioned too frequent bathing and rubbing; too long-continued baths; maceration of the skin from sweat; acid and alkaline excretions left in contact with the skin; contact with secretions from irritated and inflamed mucous membranes; various physical and chemical agencies; too warm bed-clothing; piercing the ears; scratching occasioned by the burning and itching such as vermin, scabies, and other conditions produce. When eczema has once broken out, these conditions prolong and aggravate it and cause it to spread. A mycotic origin of eczema has been suggested, but cannot as yet be regarded as proved. It is, however, highly probable, from the configuration, localization, and obstinacy to treatment, that parasitic eczema does exist.—*Journal of Cutaneous and Genito-urinary Diseases.*

Twenty-five Cases of Nephrectomy by Abdominal Section.—At a meeting of the Medico-Chirurgical Society Mr. Knowsley Thornton read a paper, and accompanied it with a complete table of twenty-five cases, showing age, sex, condition, disease, date of operation, situation of incision, method of treating ureter, whether drained or not, immediate result, and subsequent history to date. Eight of the cases had already been brought before the International Medical Congress in Copenhagen, and these were marked off from the seventeen unpublished cases in the table, and but briefly, if at all, referred to in the context. Of one of them, No. 6, which was reported a failure in 1884, with pain in the bladder and the other kidney, a very satisfactory subsequent history was now given, the patient being in perfect health, married, and mother of a son. There were twenty recoveries and five deaths in the series, a result twenty per cent. better than that generally given for all nephrectomies, including those by lumbar section. This result was compared with that in ovariotomy eleven years ago, the mortality being then much higher for this comparatively simple operation. Two of the fatal cases were pointed to as not properly to be counted against abdominal nephrectomy, one being a malignant tumor which had perforated the right pleura, and the other having died of hemiplegia, which was brought on by the anæsthesia rather than by the operation. The superiority of nephrectomy over nephrotomy and drainage for the cure of hydronephrosis was illustrated by six cases. Incision of suppurating kidney as a preliminary to nephrectomy was condemned. The author's practice of pinning out the ureter had led to no troubles, and was claimed as the chief factor in success. The removal of suppurating kidneys without any puncture during operation was strongly advocated whenever their size admitted it. The superiority of Langenbuch's incision was insisted upon. The question of drainage was fully discussed, and that of the differential diagnosis in sarcoma of the capsule and of the kidney touched upon. A question was raised as to the varieties of tubercular (so-called scrofulous) kidney; and the paper concluded with a promise of records of lumbar and abdominal nephrotomies and nephrolithotomies, in which the mortality was considerably lower than in nephrectomy. Either figures or actual specimens were shown of many of the cases. Mr. Clement Lucas claimed that the lumbar operation was more successful than the anterior method. He had operated on six cases without a death, and considered this success due to careful selection of the cases. He insisted on the importance of knowing the working power of the other kidney; the quantity of urea excreted daily should be estimated, and if it were less than half the normal amount, then the operation must be a very serious one. His cases included hydronephrosis, pyonephrosis, and calculous pyelitis; but he had not operated for malignant disease of the kidney. Twice he had explored the loin, but finding the lumbar glands involved he had abandoned the operation. Czerny taught that hydronephrosis was best dealt with by laying open the cyst and stitching the wall to the skin: this was absolutely wrong. The cyst should be removed, for in hydronephrosis it was generally possible to estimate the condition of the other kidney. He questioned whether suppurating kidneys could be removed through the peritoneum with perfect safety, owing to the danger of fouling the serous membrane. The ureter had never given him any trouble; he simply ligatured it and dropped it back. Mr. Thornton said that he did not hope to convert Mr. Lucas to the anterior operation, though he congratulated him on his successful cases. It must be remembered that when a large number of cases were dealt with then the mortality came in. In his first eleven cases all recovered, but in the next fourteen he lost five cases, giving a mortality in the twenty-five of twenty per cent. He agreed that it was important to estimate the condition of the other kidney, but thought that a little risk might be run, even if it were not quite sound, because the labor thrown upon it by a fellow-suppurating kidney would be greater than that thrown upon it by the operation. He had not met with any difficulty in preventing septic injection of the peritoneum. He defended his mode of dealing with the ureter.—*The London Medical Recorder.*

Hydrate of Chloral in Chapped Nipple.—Mitropolsky, of Moscow, recommends chloral as an excellent local means for fissured and excoriated nipples. The latter should be kept covered with compresses (soft linen) soaked in a solution of half a drachm of chloral in three ounces of water. The compresses should be changed every two and a half or three hours. When a prolonged application is necessary, it is advisable to use a weaker lotion (half-drachm to six ounces). The solution leaves a thin, whitish, firmly adherent film over the diseased surface, which does not disappear by suckling. Pain and tenderness are said to be strikingly relieved almost immediately; the lesions rapidly healing. The chloral compresses do not produce any bad effects on nurslings.—*St. Louis Medical and Surgical Journal.*

---

Another Attack on American Industries.—The Austrian authorities recently made a raid on the drug-stores in Vienna and confiscated all the "safe-cure" preparations they could lay their hands on.

## NATIVE AMERICANS AND IMMUNITY FROM PHTHISIS.

IN an interesting article on the subject of phthisis (*Medical Age*, June 25th), Dr. E. P. Hurd presents some facts which show, as he thinks, a slowly acquired immunity among native Americans against this disease. Dr. Hurd has compiled the statistics of mortality in the city of Newburyport for the past thirty years with the following result:

*Population of American Parentage.*

1858, one death from consumption in 378
1865 " " " " " 564
1870 " " " " " 252
1875 " " " " " 300
1880 " " " " " 351

*Population of Foreign Parentage.*

1858, one death from consumption in 273
1865 " " " " " 150
1870 " " " " " 161
1875 " " " " " 176
1880 " " " " " 136

The yearly average among persons of American parentage is one death from consumption in 336. The yearly average among persons of foreign parentage is one death from consumption in 179.

"The lesson taught by these tables," says Dr. Hurd, "is that consumption is far more prevalent among foreigners than among natives; as far as the latter are concerned, there is a gradual decrease in the death-rate from this disease."

Dr. Snow, of Providence, R. I., has also computed statistics which show the same thing. For example:

*Population of American Parentage.*

1875, one death from consumption in 415
1880 " " " " " 435

*Population of Foreign Parentage.*

1875, one death from consumption in 288
1880 " " " " " 268

Dr. Hurd's theory that the native American race is securing some immunity against phthisis, while the bacillus attacks especially the immigrants who are being sloughed upon our shores, has a certain amount of attractiveness—for the natives. He does not, however, take fully into account the fact that the foreign population are, as a rule, not so well housed or fed, and that they in general live under much worse hygienic conditions. If the mortality-rate from phthisis is increasing among them, it is largely because of the well-known fact that we are getting a much lower grade of immigrant than we used to receive.

## BIRTH RETURNS.

ACCORDING to the *New York Herald*, Massachusetts has a new statute, which has just gone into effect, for securing a more perfect record of vital statistics. All doctors are required to report births, and for each birth reported the doctor gets a fee of twenty-five cents. No penalty is fixed for failure to report. This little fee is no great object, yet it is proper as recognizing that the State has no right to exact a gratuitous service from medical men—which it does when it calls for a whole series of certificates that must be given under penalties for failure, as with doctors in this city. The language of the Massachusetts statute is odd. It requires the doctor to report all births "at which he is present." Suppose the baby is born before the doctor gets there?

The New York County Medical Association has a special committee for the purpose of considering this matter of certificate-grievance, with the view of securing as well more complete returns. A professional friend solemnly assures us that half his life is spent in writing certificates for life insurance, schools, judges, societies, and all kinds of health organizations. Great Britain and, we think, Germany wisely throw the responsibility of returning births upon the parents themselves. At all events, the legal opinion is that the State has no power to impose any service without providing a compensation.

## A GOOD WORD FOR THE GYPSIES.

IN the minds of most people a vagabond is a vagabond and a tramp is a tramp, without distinction or difference, except, possibly, that each individual seen is dirtier than the preceding, in proportion as the season is further advanced, and the dust has accumulated in ever-increasing thickness on his unwashed hide. This belief is well enough founded concerning the common tramp, that strange by-product of Anglo-Saxon civilization. But it is unjust to class with him that other race of vagabonds, the gypsy that comes no man knows whence, and that is not seemingly a degenerated stock but has ever been as it is now, a semi-heathen and a nomad race, living among and on, yet not of, the Christian and civilized communities of Europe and America. The gypsies are vagabonds, perhaps, but they are not tramps in the common acceptation of the term. They may be lacking in honesty, yet they are not without honor; they are proud of their lineage, and they are clean in their persons and in their homes.

This last statement may strike some of our readers as rather strange, yet it is corroborated by no less an authority than Mr. E. L. Wakeman, than whom no one in this country is better qualified to speak concerning the mode of life and customs of this peculiar people. In an interesting article in the *Annals of Hygiene* for May, 1889, Mr. Wakeman treats of gypsy hygiene, and shows that many of our own race might well imitate these despised people in their worship of cleanliness. He says that, during a close study of the race in many lands, for more than a quarter of a century, he has never known a physically unclean gypsy, the only exceptions being a few in-

dividuals in the towns of Southern Hungary and in Havana. The gypsy camps are always pitched near a spring or a stream, and the morning bath is as certain as the morning itself. But the cleansing is not of the skin alone, the undergarments are as constantly washed, and the straw bedding is likewise daily spread out for a sunning and airing.

But it is not in cleanliness alone that the gypsies compare favorably with those of the higher races among whom they live. Their virtue is absolute. Concerning this Mr. Wakeman says: "While gypsies are without law, as we know it, no people live who more rigorously follow, in fact and to the ultimate of spirit, the highest and purest code of physical and moral observance. They universally revere the marriage relation. I say universally, and use that word unqualifiedly. There is not an exception. . . Such a thing as disloyalty of wife to husband, or husband to wife, after marriage, has yet to be recorded of gypsy on the European or American continents." Furthermore, before marriage, there is not with them, either in theory or in practice, one law for men and another for women, but they regard chastity as essential a virtue in man as it is in woman.

Physical and moral cleanliness are cardinal virtues indeed, and, whatever his other shortcomings may be, the gypsy has in them good reason for his pride of race, and we cannot blame him, when he sees those virtues so little prized among his neighbors, for looking upon them as inferior beings, and unworthy of association with the Romany.

## MEDICAL MEN AND THE LAND-TAX THEORY.

THE columns of THE MEDICAL RECORD are hardly suitable for the discussion of economic problems, unless they relate very closely to the welfare of medical men. We cannot, however, refrain from referring to the fact that a number of communications have lately been received by us bearing upon the single-tax theory of Mr. Henry George. Our correspondents are all devout believers in single-tax and are, in particular, of the opinion that the adoption of Mr. George's views would vastly alleviate the condition of medical men.

It is interesting to find that the new propaganda has reached and affected so extensively medical men. In a liberal profession it is proper that every valuable idea should be received and discussed with candor. Perhaps physicians will view the single-tax idea with especial favor because, as one of our correspondents, Dr. David DeBeck, writes us, it was a physician, Quesnay, Court Physician to Louis XVI., who first proposed this "*impôt unique.*"

So far as we can learn, economists generally are agreed that land is the best thing to put taxes on, though it is a little hard to see how we can raise our $700,000,000 of local taxes on our $10,000,000,000 worth of land; or abolish poverty by shifting a tax which forms but seven per cent. of our total production.

We must take exception, also, to the view of one of our correspondents, who thinks that by lessening rents the tenement-house problem could be solved. This is sheer nonsense, as everyone who has observed the gregarious habits of the working people know. They would rather live together in small and dirty houses than go to the suburbs and live in some degree of isolation.

We cannot, however, undertake to introduce economic controversies into these pages. We are inclined to think that medical men, as a whole, will prefer to follow the inductive work of Mr. Edward Atkinson to the brilliant reasonings of doctrinaires.

## THE INFLUENCE OF HYPNOTICS ON THE PROCESS OF DIGESTION.

PROFESSOR CRAMER has made a study of the process of digestion as influenced by some of the hypnotics now commonly employed. Chloral, paraldehyde, hydrate of amylene, and sulphonal were tested relative to their influence on the saliva, the gastric juice, and pancreatic secretion. Cramer employed the method of artificial digestion. The results of his researches are published in the *Therapeutische Monatshefte.* His conclusions are, briefly, as follows:

1. The diastatic action of mixed saliva is not interfered with by the drugs referred to. 2. The capacity to digest fibrin is not reduced by weak solutions of chloral, paraldehyde, amylene hydrate, and sulphonal. But in a more concentrated form (1 to 20) the three first-named substances retard this action unmistakably. On account of the insufficient solubility of sulphonal, reliable results were not obtained with it. 3. The functions of the pancreatic juice were markedly influenced by chloral and paraldehyde, less so by hydrate of amylene, and not at all by sulphonal.

It follows, from these observations, what, indeed, many physicians have already learned from their own experience, that none of the hypnotics are to be indiscriminately dispensed and, more particularly, that caution is necessary where digestion is already impaired.

# News of the Week.

ACTINOMYCOSIS IN NEW YORK CITY.—The death of a man in this city from actinomycosis of the liver was recently reported.

THE MEETING OF THE AMERICAN RHINOLOGICAL ASSOCIATION, which was announced for August 28th, has been postponed until October 9, 10, and 11, 1889, at which time it will be held at the Palmer House, Chicago.

DR. CLARA BLISS HINDS, daughter of the late Dr. D. A. Bliss, General Garfield's physician, is practising in Washington, and is an active member of the Woman's Anthropological Society of that city.

DR. WEBER-LIEL, formerly of Jena, where he was at one time Professor of Otology, and had to resign on account of ill health, has now recovered and has resumed the practice of his specialty at Bonn.

THE LEHIGH VALLEY MEDICAL ASSOCIATION will hold its Ninth Annual Meeting at Glen Summit, Pa., on Friday, August 26th.

INSANITY IN RUSSIA.—An official report recently made to the Russian Government states that insanity is increasing very rapidly in that country. The majority of those affected belong to the middle and upper classes, and the years immediately succeeding puberty are those in which the disease declares itself in the greater number of cases.

THE RESIGNATION OF DR. DAY.—The following communication was sent to Dr. Day after the acceptance of his resignation as Sanitary Superintendent:

NEW YORK, July 30, 1889.

DR. WALTER DE F. DAY:

*Dear Sir*—The Board of Health directs me to inform you that it has this day, with great reluctance, accepted your resignation of the office of Sanitary Superintendent, which you have long filled to the entire satisfaction of the public and of this Department, and with great honor to yourself.

The Board desires me to officially express to you its high appreciation of your valuable services as the Chief Executive Officer of this Department, of your ability and integrity, and of your uniform kindness and courtesy in all your official relations. The Board regrets that your health obliges you to dissolve your connection with this Department, and thereby deprives it of the services of an officer who has its entire confidence.

Very respectfully, and by order of the Board,

(Signed) EMMONS CLARK, *Secretary.*

DR. W. A. EWING has been appointed Sanitary Superintendent of the Board of Health in place of Dr. Day. Dr. Ewing is well and favorably known to many physicians of this city as a talented and hard-working practitioner, and there is every reason to believe that his administration of this department will not suffer in comparison with that of his predecessor, difficult as the task may be for one who has to follow Dr. Day.

THE NOVA SCOTIA MEDICAL SOCIETY held its annual meeting in Halifax on July 3d and 4th. The attendance was fairly large. The President, Dr. Campbell, delivered an address upon "Medical Legislation in Nova Scotia." The following papers were read the first day: "The Progress of Medicine," by Dr. J. C. De Witt; "Pneumonia," by Dr. Buckley; "An Epidemic of Typhoid Fever at Truro," by Dr. W. S. Muir; "The Latest Methods of Treating Wounds," by Dr. Reid; "Surgical Dressings," by Dr. John Stewart; "Keloid," by Dr. Parker; "The Importance of Early Operations in Cancer," by Dr. Farrell; and "Report of a Case of Cancer of the Breast," by Dr. Muir. On the second day of the meeting Dr. Page presented a communication on "The Frequency of Forceps Application;" Dr. Fox, one on "Puerperal Eclampsia;" Dr. N. E. McKay, on "Hare Lip;" Dr. Stoddard, on "The Disposal of Sewerage;" Dr. Morrow, on "The Use and Function of Medical Journals," and Dr. W. B. Moore, on "The Therapeutic Value of Glycerine." Dr. W. B. Moore, of Kentville, was elected President, and Dr. W. S. Muir, of Truro, Secretary, for the ensuing year.

THE MEDICAL SOCIETY OF WEST VIRGINIA.—The annual meeting of this Society was held at White Sulphur Springs, on July 17, 18, and 19, 1889. The address of welcome was delivered by Dr. T. R. Evans, of Charleston, and then the President, Dr. L. D. Wilson, of Wheeling, read the annual address. He referred in the opening to the creation, during a special session of the Legislature, of a State Board of Health, and then passed on to a consideration of the advances in medical science during recent years. Dr. D. Mayer read a paper on the value of Crockett Spring, Montgomery County, Va. The water in this spring is 70° in the coldest weather. The essayist recommended the water for rheumatism, gout, and diseases of that nature. Dr. L. B. Edwards, of Richmond, spoke upon the advantages of State Medical Examining Boards. Dr. Hoopman, of Baltimore, then read a paper on the "Pathology of Fever." Dr. Upshur, of Richmond, read a paper on "Reflex Bladder Troubles," which was discussed by Drs. Hunter, McGuire, Richardson, and others. A communication, entitled "Two Laparotomies, with Comments," was presented by Dr. J. E. Michael, and one on the "Care of our Females from Birth to Maturity," by Dr. J. D. Myers, of Huntington. The speaker had a rather poor opinion of the physical powers of women of the present day, saying that one hundred years ago one woman could do the work of six in our day. Children, he said, should be made to sleep in the dark. A child who has always slept in the dark will not be always looking under the bed for the burglar, nor will she jump on a chair if she see a mouse or rat. He condemned high-heeled shoes, and said that no girl should marry before she is twenty years old. The following officers for the ensuing year were elected: *President*, Dr. S. H. Austin, of Lewisburg; *1st Vice-President*, Dr. T. R. Evans; *2d Vice-President*, Dr. J. D. Mayer, of Charleston; *3d Vice-President*, Dr. Moss, of Cabell County. Dr. Fullerton, of Charleston, the present incumbent, was re-elected *Secretary*. Dr. Campbell, of Wheeling, was re-elected *Treasurer*. *Board of Censors*—Drs. McDonald, Enslow, Putney, Fraval, Rupert, Hughait, and Wagner. The next meeting of the Society will be held in Wheeling. The number of members is now nearly two hundred.

JOHN HOWARD PRIZE.—The Russian Government offers a prize of $400 and a gold medal for the best essay on "John Howard in the History of Prison Reform," in memory of the British philanthropist, who died at Kherson, in South Russia, in 1790, after doing much toward the improvement of the prisons in Russia. The prize is open to general competition, but the essays must be written either in Russian or in French. They are to be sent to St. Petersburg, when they will be judged by a select committee during the convocation of the fourth International Prison Congress, which takes place next year during the centenary of John Howard. There is ample room for prison reform in that free and enlightened country.

AN ALL-EMBRACING SPECIALIST.—A physician in an Iowa town, who is given to advertising, has on one of his display cards, printed on the same sheet with the butchers, soap-makers, and confectioners, the following: "Practice limited (except among former patrons) to Surgery, Diseases of Women, Diseases of Respiratory, Alimentary, and Genito-urinary Organs. The Eye, Ear, and Skin. A general Office and Consultation Practice."

"LE JOURNAL DES MALADIES CUTANÉES ET SYPHILITIQUES" is the title of a new dermatological journal which has appeared in Paris. The editor-in-chief is Dr. Henri Fournier. The journal is to appear twice in each month.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION will hold its next meeting at Evansville, Ind., September 10th, 11th, and 12th.

Dr. Edward J. Turner died of nephritis at his home in Wilton, Conn., on July 26th. Dr. Turner was born in Bath, Me., in 1822. He was known as the founder of the inebriate asylum, and his whole professional life was passed in controversies upon the subject of inebriety as a disease. After twenty years of labor, against great opposition, he finally succeeded in founding the Inebriate Asylum at Binghamton, the first ever built. Since that time over seventy asylums have been established in different parts of the world. The Binghamton asylum was afterward changed to an insane asylum, and at the time of his death Dr. Turner was endeavoring to have it changed again to its original purpose, and was also engaged in trying to establish an asylum for female inebriates. While not the originator of the idea of inebriety as a disease, he was one of the earliest upholders of this view, and was the first to urge the treatment of inebriety in asylums.

Dr. A. E. Jones, of Cincinnati, was murdered on July 25th by his colored coachman, the object being apparently robbery. Dr. Jones was a well-known physician, and a prominent citizen of Cincinnati, having been for several years a member of the Common Council. During the war he was appointed provost-marshal, and was always greatly interested in military affairs, being at the time of his death Surgeon-General of the Ohio National Guard.

The Eyes of School-children.—Dr. T. F. Bliss, of Springfield, O., recently made an examination, at the request of the School Board, of the eyes of the children attending the public schools of that city. The number of pupils examined was 3,707, of which 378 had some defect of vision, or some disease of the eye, or both, divided as follows: Granular ophthalmia, 13; chronic conjunctivitis, 14; inflammation of lids, 8; strabismus, or cross-eye, 37; low vision not improved by test-glasses and less than one-fourth normal, 24. In the remainder there was defective vision which was improved by test-glasses.

A Library Three Thousand Five Hundred Years Old.—At the annual meeting of the Philological Society of Great Britain, held on July 1st, a paper by Professor Sayce was read on the recent discoveries in the palace of Amenophis III. From the tablets and inscriptions there found we learn that in the fifteenth century before our era—a century before the Exodus—active literary intercourse was going on throughout the civilized world of Western Asia, between Babylon and Egypt and the smaller states of Palestine, of Syria, of Mesopotamia, and even of Eastern Kappadokia. And this intercourse was carried on by means of the Babylonian language, and the complicated Babylonian script. This implies that all over the civilized East there were libraries and schools where the Babylonian language and literature were taught and learned. Babylonian appeared to have been as much the language of diplomacy and cultivated society as French has become in modern times, with the difference that, whereas it does not take long to learn to read French, the cuneiform syllabary required years of hard labor and attention before it could be acquired. We can now understand the meaning of the name of the Canaanitish city which stood near Hebron, and which seems to have been one of the most important of the towns of Southern Palestine. Kirjath-Sepher, or "Book-town," must have been the seat of a famous library, consisting mainly, if not altogether, as the Tel el-Amarna tablets inform us, of clay tablets inscribed with cuneiform characters. As the city also bore the name of Debir, or "Sanctuary," we may conclude that the tablets were stored in its chief temple, like the libraries of Assyria and Babylonia. It may be that they are still lying under the soil, awaiting the day when the spade of the excavator shall restore them to the light. The literary influence of Babylonia in the age before the Israelitish conquest of Palestine explains the occurrence of the names of Babylonian deities among the inhabitants of the West. Moses died on the summit of Mount Nebo, which received its name from the Babylonian god of literature, to whom the great temple of Borsippa was dedicated; and Sinai itself, the mountain "of Sin," testifies to a worship of the Babylonian Moon-god, Sin, amid the solitudes of the desert. Moloch or Malik, was a Babylonian divinity like Rimmon, the Air-god, after whom more than one locality in Palestine was named, and Anat, the wife of Anu, the Sky-god, gave her name to the Palestinian Anah, as well as to Anathoth, the city of "the Anat-goddesses." In a careful reading of the tablets Canon Sayce came upon many ancient names and incidents known up to the present only from their appearance in the Bible. All these he carefully described, as well as several references in the tablets to the Hittites.

Meeting of the American Medical Association.—Dr. Vaughan, of Michigan, writes that he was reported as saying that Koch did not believe the Eberth germ to be the cause of typhoid fever, whereas he said that Koch did not believe the Eberth germ to be demonstrated to be the cause of typhoid fever. The thyrotomy reported by Dr. Ephraim Cutter was performed in 1866 instead of 1886. It was Dr. Jenkins, and not Dr. Jaggard, who discussed the paper on dioscorea villosa, or wild yam.

Bees and Rheumatism.—A remedy for rheumatism, that is said to be popular in France, consists in exposing the patient to the stings of bees. The insects are applied to the neighborhood of the affected part and the stings are repeated until a cure results. In a memoir presented to the Academy of Medicine of Paris, a report is given of over one hundred cases of acute and chronic rheumatism so treated with success. It required, however, an average of nearly three hundred and fifty stings for each case. Some patients might prefer the disease to the remedy.

The Austrian Pharmacopœia.—The seventh edition of the Austrian Pharmacopœia will soon be published. It will not contain many alterations. The proportion of hydrocyanic acid in cherry-laurel water will be raised from 0.6 to 1 per mil., and that of arsenic in Fowler's solution will be reduced to 1 per cent. Zittmann's decoction will henceforth be called compound decoction of sarsaparilla, and Dover's powder will be known as pulvis ipecacuanhæ opiatus.

The Length of the Medical Students' College Course.—The German Medical Congress has resolved that the obligatory period of medical study, including the term of military service, should be fixed at not less than five years.

## Society Reports.

### THE EIGHTH GERMAN CONGRESS OF INTERNAL MEDICINE.

*Held at Wiesbaden, April 15, 16, 17, and 18, 1889.*

UPON the opening of the first session of the Congress

THE PRESIDENT'S ADDRESS

was delivered by HERR VON LIEBERMEISTER, of Tübingen. The subject of the address was "The Scope of Internal Medicine." This was, he said, not a branch of medical science, but medical science itself, the trunk from which surgery, gynecology, ophthalmology, laryngology, and all the other branches sprang. The problems which the specialists were called upon to solve were easy compared to those which confronted the general practitioner, and internal medicine could advance only by dint of hard and unremitting labor. But in addition to these purely medical subjects, general medicine had also its public duties to perform. It stood in the relation of a guardian to the public in all things that had to do with health. It must warn the people against the dangers which threaten them in the neglect of hygienic rules, and it must also guard them against the attacks of quackery. After a few well-chosen words of greeting to his fellow-members, the speaker declared the Congress open.

HERR SCHULTZE, of Bonn, delivered a eulogy upon Professor Hugo Rühle, who had died on July 11, 1888, aged sixty-four years. He was one of the earliest members of the Congress, and had always been active in its interests.

INTESTINAL OBSTRUCTION.

HERR LEICHTENSTERN, of Cologne, opened the discussion with a brief reference to the history of this affection, which was recognized by the earliest medical writers. The most important contributions to our knowledge of the nature and treatment of the condition, however, date from comparatively recent times. The first employment of the term "ileus" was to designate disease of the ileum; later it came to be applied to intestinal obstruction accompanied by stercoraceous vomiting; but now it is used to denote intestinal occlusion simply, which may or may not present vomiting of fecal matter as one of its symptoms. Intestinal obstruction may be due to mechanical causes, or it may arise from paralysis of the muscular coat; but in the majority of cases both conditions are present. The most frequent

CAUSE OF ILEUS

is peritonitis, and especially perityphlitis. It may also follow injuries of the abdomen, the reduction of a hernia, laparotomy, or even the removal of some mechanical obstruction. Here the obstruction is a paralytic one. Excessive meteorism may also occasion it by inducing a paralysis of the muscular coat. The paralytic form may also lead to mechanical obstruction by the formation of a sharp bend at either or both extremities of the paralyzed portion.

The sudden occurrence of symptoms of intestinal occlusion does not necessarily imply a sudden formation of the obstruction. There may be well-marked obstruction which remains concealed because of the hypertrophy of the portion of intestine above it. After a time, as a result of inflammatory changes in the mucous membrane, or from some other cause, the muscular coat becomes paretic; it is then unable to drive the contents of the intestine beyond the constriction, and the condition at last declares itself by unmistakable signs.

In the

DIAGNOSIS OF ILEUS

we have first to ascertain the cause of the obstruction, whether it lie in the intestine itself, in the peritoneum, or in other of the abdominal organs; secondly, the nature of the obstruction, whether it be from gall-stones, from fecal impaction, from peritoneal bands, from paralysis of the muscular coat, etc.; and finally, the seat of the obstruction. The signs pointing to occlusion of the small intestine are the sudden onset of the symptoms, copious vomiting, contraction of the upper portion of the abdomen, and the presence of indican in the urine. When the large intestine is the seat of the obstruction, the symptoms are more gradual in their onset and are less intense, the abdomen is unevenly distended, and the portions of the large intestine can be felt as distended masses, often displaced as a result of this distention. The lower down the seat of occlusion, the longer will have been the interval between the appearance of the constipation and the onset of the more acute symptoms.

THE SYMPTOMS OF ILEUS

are those directly due to the intestinal obstruction, such as constipation, pain, and stercoraceous vomiting. True fecal matter is seldom vomited, and what is called fæces is simply the contents of the small intestine having a fecal odor. Other symptoms are general, and are due to the absorption of the products of decomposition or to reflex causes. These are fever, delirium, collapse, etc.

HERR CURSCHMAN, of Leipsic, continued the discussion, taking for his subject the

TREATMENT OF INTESTINAL OBSTRUCTION.

The speaker said that every physician should have an outline of the treatment to be pursued always in his mind, as the suddenness of the symptoms demanded prompt action, with a clear idea of the end sought for and of the means best adapted to that end. He uttered some words of caution against a resort to laparotomy in all cases without distinction. In some cases, indeed, the danger of an operation was not less than that of the ileus itself. When a patient is not seen until collapse is imminent, if not actually present, and when the physician is able to form only the most vague idea of the nature and seat of the obstruction, the outlook of surgical treatment is in no degree better than that of medical. On the other hand, the rule to operate early is more easily formulated than carried out. It is no light matter, for either physician or patient, to consent to an operation at the very beginning of a trouble which, as statistics prove, yields to internal treatment alone in over one third of the cases. Nevertheless, when it is possible early in the progress of the affection to make a diagnosis of the seat and of the cause of the obstruction, it would certainly be wrong not to operate.

MEDICAL TREATMENT OF ILEUS.

The diet must be absolutely restricted, thirst being controlled by cracked ice or small enemata of water. Purgations should on no account be given, but opium is to be used freely to restrain the peristaltic movements. Washing out the stomach, as recommended by Kussmaul, is useful, as it not only relieves the distention of this viscus, but even tends to reduce the pressure in the intestine by emptying it in a measure of its contents. Puncture of the intestine with a hollow needle, in order to give exit to the gas, is a measure often of great benefit. The speaker was decidedly opposed to the use of fluid injections, which he looked upon as dangerous, but favored gaseous injections as recommended by von Ziemssen.

HERR JÜRGENSEN, of Tübingen, agreed with the last speaker as to the utility of puncture of the intestine for the withdrawal of gas, but he did not regard with favor the employment of gaseous enemata. They caused an increase of the intra-abdominal pressure, and he had even seen a fatal case of general emphysema and pneumo-tho rax caused by the escape of gas from the rectum into the retroperitoneal connective tissue.

HERR ROSENBACH, of Breslau, referred to a sign of considerable value furnished by the examination of the urine. If the urine is boiled and then nitric acid added, gradually a red color is developed, and on shaking the bub-

bles assume a violet tint. This reaction is not the same as that of indican. It denotes the decomposition of albuminous bodies in the tissues, and not the presence of products of intestinal decomposition. The persistence of this reaction for more than two weeks is of very grave prognostic import. The speaker regarded puncture of the intestine as a measure of great value.

HERR NOTHNAGEL, of Vienna, dwelt upon the question of intussusception, which he did not regard as a very frequent cause of intestinal obstruction.

HERR VON ZIEMSSEN, of Munich, had never seen any evil effects follow the injection of air, yet he thought it should be done with care. From his personal experience in an attack of ileus, he had come to regard the administration of drugs by the stomach as useless, and had found them effective only when given hypodermatically or by the rectum. He was in favor of perforation of the intestine with a hollow needle, and had often seen great relief from this measure.

HERR FÜRBRINGER, of Berlin, said that in the Friedrichshain Hospital thirteen per cent. of the cases of ileus recovered without operation. The results of medical treatment are not bad enough, and those of surgical treatment not good enough, to justify a resort to operative measures in all cases. He thought opium was the best drug in most cases. He was in favor of puncture of the intestine, yet at the autopsies of cases so treated he had occasionally seen evidences of peritonitis caused thereby. He had seen one case of rupture of the intestine following puncture.

HERR HOFFMANN, of Leipsic, had had some unpleasant experiences after puncture of the intestine. He was greatly in favor of laparotomy, an operation in itself without much danger, and one which was becoming every day more and more safe.

HERR SCHEDE, of Hamburg, thought that the future of surgical measures depended greatly upon the advances made in diagnosis of the seat and character of the obstruction. The danger of operation was due rather to the previous critical condition of the patient. If a certain diagnosis could be made in acute cases, he would resort at once to surgical measures, but otherwise he would try, first, medical means. At the first indication of heart failure, however, he would operate.

HERR FLOTHMANN, of Ems, reported four cases successfully treated by operation.

HERR BÄUMLER, of Freiburg, favored the use of opium in all cases, even though surgeons claimed that it often caused an apparent improvement, and thus operative treatment was postponed and much valuable time was lost. He believed in surgical measures only in cases of very acute strangulation. He had had success with internal treatment in even the most severe cases.

HERR LEUBE, of Würzburg, said the question divided itself into two, viz., when *may* the surgeon operate, and when *must* the surgeon operate. The surgeon *may* operate in cases in which all medical resources, such as opium, washing out the stomach, and purgatives (in the general condemnation of which he did not join) had been tried in rapid succession without success. The surgeon *must* operate upon the first indication of a failing pulse.

HERR IMMERMANN, of Basle, read a paper on

THE FUNCTIONS OF THE STOMACH IN PULMONARY PHTHISIS.

He had made a series of investigations on fifty-four phthisical patients to determine the digestive power of the stomach, and had found digestion to be normal in all cases, very little disturbance being present even in febrile cases. He concluded, therefore, that the anorexia, so common in pulmonary phthisis, was nervous and wholly independent of structural changes in the gastric mucous membrane. The logical deduction from this was that forced feeding in phthisis was a rational measure.

HERR PETERSEN, of Copenhagen, read a paper on

THE HIPPOCRATIC METHOD

of following nature and aiding her in the cure of disease. He thought this was too much neglected in these days, and believed that truly practical medicine must work along the lines of Hippocratism.

HERR FÜRBRINGER, of Berlin, read a paper on

IMPOTENCE IN THE MALE,

referring especially to the nervous form. The prognosis is not very favorable, the speaker having obtained a cure in only about one-third of his cases.

HERR DETTWEILER, of Falkenstein, exhibited

A POCKET SPITTOON FOR PHTHISICAL PATIENTS.

It consisted of a bottle with a funnel-shaped opening which was closed, when not in use, by a screw-cap.

HERR KLEMPERER, of Berlin, read a paper on

DILATATION OF THE STOMACH, AND ITS TREATMENT.

The cases which he had studied were not consequent upon stricture. In most of them there was hyperacidity of the gastric secretions. In some there was good muscular power in the walls of the stomach, in others the motor strength was diminished. In the treatment of this condition washing out the stomach held the first rank. This was best done in the evening, and with the use of but a small quantity of water. In regard to food, meat should be forbidden, the chief reliance being placed on the carbohydrates and fats, such as cream, sugar, bread, and butter. Other remedies which he had found to be of value were massage, electricity, creosote, and alcohol.

HERR HANAU, of Zürich, reported two cases of

SUCCESSFUL INOCULATION OF CANCER.

He used pieces of cancer taken from a white rat, which he inserted into the scrotal tissue of two other rats. Two months later one animal showed a general peritoneal carcinosis, and the other had carcinomatous nodules in the scrotum. Histologically the inoculated cancer was the same as that from which the inoculations were made.

HERR LAUENSTEIN, of Hamburg, read a paper on

STRICTURE OF THE PYLORUS.

His report was based upon the study of twenty cases—eleven of carcinoma, seven of cicatrices following ulcer, one of duodenal stricture (indistinguishable clinically from pyloric stricture), and one of compression of the pylorus from without by a large gall-stone. Tumors of the pylorus, when the stomach is of moderate size, are found in the epigastrium at the level of the eighth or ninth costal cartilage. When the stomach is empty the tumor lies a little more to the left, and moves over to the right when the stomach is full. When there is marked gastric dilatation the movements of the tumor are more extensive. Sometimes the tumor cannot be felt except when the stomach is empty. Tumors following ulceration lie somewhat deeper, as a rule, than cancer, and frequently form adhesions with the mesocolon or transverse colon.

TREATMENT OF PYLORIC STENOSIS.

There are three operations which may be undertaken for the relief of strictured pylorus, the choice of which can be made only after the abdomen has been opened. The first operation is the plastic one of Heineke and Mikulicz, which is of service in cases of non-malignant stenosis. The second consists in the establishment of a gastro-intestinal fistula, and is applicable to cases of cancer or of ulcerative stricture which cannot otherwise be relieved. This operation can be performed in less than an hour, and is less dangerous than resection of the pylorus. The third operation is resection, and is occasionally of service in cases of non-adherent cancer. The operation is a tedious one, and apt to be dangerous to the patient.

HERR ROSER, of Hanau, presented a patient upon whom he had performed

TOTAL EXTIRPATION OF THE LARYNX

on account of carcinoma. The hyoid bone was also removed.

HERR FINKELNBURG, of Bonn, read a paper on

THE RELATION OF THE SOIL TO THE SPREAD OF TUBERCULOSIS.

A stagnant condition of the subsoil water would seem possibly to favor the production of the disease.

HERR VON ZIEMSSEN presented a communication upon the

MOVEMENTS OF THE HUMAN HEART,

in which he detailed the results of a series of observations he had made upon the heart movements in a boy fourteen years of age, in whom the organ was exposed after a resection of the ribs.

HERR KREHL, of Leipsic, read a paper on the

VARIATIONS OF INTRA-CARDIAC AND ARTERIAL PRESSURE,

in which he described a series of experiments, on dogs, made by Frey and himself.

HERR EBSTEIN presented a paper on

THE NATURE OF GOUT.

He recognized two forms of the disease, according as the process was primary in the articulations or in the kidneys. Primary articular gout is essentially a chronic disease, interrupted by acute exacerbations which are known as the "attacks." The speaker did not believe that the deposits occurred in consequence of inflammation, but he regarded uric acid as a chemical poison which excited, not an inflammatory but a necrotic process. We may have very serious gouty lesions, caused by the presence of uric acid in the tissues, without having any deposits. In renal gout there is a stagnation of uric acid, together with anatomical or functional alterations in the kidney. But this is not the cause of the deposits in the tissues, in the articular form of the disease. In this form there is an excessive production of uric acid in the medulla of the bones and in the muscles, whence it passes into the lymphatics, and thus gets into the blood, and is finally excreted by the kidneys. But juices rich in uric acid pass with difficulty through the lymphatics, and this is the true reason for the deposits.

HERR PFEIFFER continued the discussion of the subject with a paper on

THE TREATMENT OF GOUT.

In regard to diet, he said that he did not favor the exclusion of meat, as such a course might serve to increase the gouty cachexia. The hydrocarbons give rise to the formation of uric acid, and should be absolutely forbidden; alcohol in any shape should not be permitted. Exercise in the open air should be taken as soon as possible, since rest only prolongs the attack. The medical treatment should consist in the administration of alkalies, preferably by means of mineral waters, both externally and internally, at the very beginning of an attack. During the height of the attack, when the pain is severe, salicylic acid and dilute hydrochloric acid are of the greatest service.

HERR KRAUSE, of Berlin, read a paper on

THE TREATMENT OF TUBERCULAR LARYNGITIS.

He advocated tracheotomy to secure rest to the organ, and then scraping of the diseased parts, followed by local application of iodoform or lactic acid.

HERR SCHEISSMANN, of Berlin, said that he had seen the best results with incisions, scarifications, scraping, and the local use of lactic acid and menthol.

HERR DEHIO read a paper on

THE VESICULAR MURMUR,

in which he maintained that this sound was produced by vibrations transmitted to the residual air in the alveoli from the column of inspired air.

HERR BASCH, of Vienna, read a paper on

CARDIAC DYSPNŒA.

This form of dyspnœa, he said, is marked by three symptoms, viz., shortness of breath, diminution of the useful effect of respiration as regards hæmatosis, and increased volume of the lungs. These last two conditions had been shown experimentally, by the speaker, to result from interference with the action of the left ventricle.

HERR FINKLER, of Bonn, related the history of an epidemic of pneumonia, observed by him, in which he found streptococcus pyogenes in every instance. He believed that the disease was due to the presence of this microbe.

HERR STORCH, of Copenhagen, exhibited

A NEW FORM OF ASPIRATOR,

which consisted of an air-tight bottle filled with water. The tube connected with the aspirator needle opened into the upper part of the bottle, while from the lower part the water was allowed to escape slowly. In this way a vacuum was caused and a considerable aspirating force was produced.

HERR MULLER, of Berne, read a paper on

THE TISSUE-CHANGES IN CARCINOMA.

He had found that in cancer there was a considerable diminution in the quantity of urea excreted, and that this was independent of any kidney trouble.

After some discussion on the papers read at this last session, the President declared the Congress of 1889 closed.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, March* 13, 1889.

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

REPORT OF THE COMMITTEE ON MICROSCOPY.

DRS. IRA VAN GIESON and JOHN S. ELY reported that the tumor of the breast referred to the committee on February 20th, by Dr. L. H. Sayre, had the morphological structure of fibro-carcinoma, or the scirrhous variety of carcinoma.

DR. JOHN S. ELY presented a specimen showing

PRIMARY CARCINOMA OF THE COMMON BILE-DUCT,

with the following remarks:

"Primary tumors of the biliary passages outside the liver, of whatever nature, are of great rarity. Two or three fibromata, a papillary myxoma, and sarcomatous infiltration of the wall of the gall-bladder have been described, but by far the commonest form of tumor of these parts is carcinoma.

"It is customary to consider separately carcinoma of the gall-bladder and of the ducts. This distinction appears to me to be properly made, since the clinical history in the two cases is essentially different, carcinoma of the biliary ducts being almost invariably accompanied by intense jaundice, while carcinoma of the gall-bladder alone never is.

"There is a considerable number of cases of so-called primary carcinoma of the gall-duct on record, but in most of these the presence of nodules of cancer in adjacent organs destroys the proof regarding the point of origin of the new growth. I have succeeded in collecting seven cases, however, in which there could be no question as to the origin of the tumor in the gall-ducts, no other growth of any kind occurring in any of these cases. These cases are reported by Durand-Fardel,[1] Rosenstein,[2] Schreiber,[3]

[1] Durand-Fardel: Recherches anatomico-pathologiques sur la Vésicule et les Canaux biliaires, Archives gén. de Méd., 1840, p. 167; also, 1841, p. 418.

Korezynski,[1] Schüppel,[2] Key,[3] and Kraus.[4] Five of the patients were men; two, women. Four were more than sixty years of age; two (Key, thirty-five, and Kraus, forty-nine) were younger; of one (Rosenstein) the age is not given. In all cases except one (Durand-Fardel) symptoms distinctly referable to the tumor were present, and they are of great uniformity.[5] There was gradually developed jaundice, which toward the last became very intense and presented all the characteristics of jaundice due to obstruction. Pain was not a marked symptom, but is mentioned as having been present in slight degree in four of the cases. The duration of the symptoms appears to have been from eight weeks to about eighteen months. The tumor in all cases was very small. In three it was situated at the mouth of the common bile-duct; in four it was in the wall of the hepatic duct. A more or less careful microscopical examination, in most of the cases, confirmed the diagnosis of carcinoma. In all the cases there was narrowing of the lumen of the gall-duct at the site of the tumor, but there was complete occlusion of it in only one, that of Kraus, in which there was a large impacted gall-stone. The biliary passages above the tumor were markedly dilated in every case, and contained liquid variously described as brownish, dirty gray, clear and slightly greenish, etc. The liver is stated to have been enlarged in four cases, and not enlarged in one; it was soft, owing to great dilatation of the bile-ducts, in three cases; firm and hard in two; in all except one (Durand-Fardel) it was deeply stained with bile. The fact that five of the seven patients died of some intercurrent disease a comparatively short time after the onset of symptoms of obstructive jaundice renders it probable that in these cases we have to do with very early stages of what would later have become more widely diffused growths involving neighboring organs. It is consequently reasonable to suppose that many of the diffused growths in the neighborhood of the gall-ducts have their starting-point in the walls of the latter.

"Through the kindness of Dr. Hartley, in whose ward the patient died, I am able to present to you this evening a specimen of this very early stage of carcinoma of the common gall-duct. The patient was a German, fifty-three years of age, a tailor. He was admitted to Bellevue Hospital on February 11, 1889, and gave the following history. Four years previously, had an attack of jaundice of short duration, from which he recovered. Present illness began four months before, when he began to be again jaundiced, but this time instead of disappearing it steadily increased in intensity. He complained of headache, loss of flesh, pain and tenderness over the liver. No vomiting, appetite good, bowels costive. Was confined to bed four weeks prior to admission. Examination showed patient to be intensely jaundiced. Tongue coated. Nothing abnormal discovered, except decided enlargement of the liver and distention of the gall-bladder, the outlines of which could be distinctly appreciated by palpation. Urine was olive green, 1.012, acid; contained a trace of albumen and a few granular casts. There was slight fever on admission (100.5° F.) and this continued, the temperature ranging between 99° and 102° F. On February 16th he was transferred to the surgical division, and five days later Dr. Hartley performed the preliminary operation for cholecystotomy. Thirty-six hours later parenchymatous hemorrhage developed, which baffled all attempts to check it, and on February 26th the patient died of exhaustion.

"*Autopsy*, eighteen hours after death. Dressings soaked with blood and about an ounce and a half of blood in abdominal cavity. Slight amount of pus at lower end of wound. No peritonitis.

"Liver much enlarged, soft, olive-green color; surface shows occasional white spots and streaks, apparently dilated bile-ducts just under the capsule. Gall-bladder and ducts very much dilated; contain whitish liquid resembling thin pus. At the mouth of the common duct there is a small nodular tumor, completely surrounding the duct and narrowing its lumen so that it is impervious to the liquid contents of the duct. The tumor is thicker in the lower and left walls of the duct, where there is a nodule measuring 11 mm. by 9 mm. The duct just above this nodule is dilated to a small pouch.

"There is no ulceration of the mucous membrane lining the duct. The cut surface of the tumor presents the appearances of carcinoma. Surrounding organs apparently not involved. Cut surface of liver shows markedly dilated bile-ducts, the walls of which appear to be very much thickened, and from which thin whitish liquid exudes; centres of lobules somewhat dark, peripheries light. Softness of liver apparently due to the great dilatation of the bile ducts.

"Pancreas somewhat hard, but no apparent lesion. Kidneys show lesions of chronic diffuse nephritis. Mesenteric glands enlarged, but no lesion evident. Stomach, intestine, and rectum normal; spleen normal; brain and thoracic contents not examined.

"Microscopical examination shows the tumor to be cylindrical-celled carcinoma; the alveoli are very thick-walled. Sections of the liver show pigmentation of the cells and dilatation of the terminal bile-ducts, the walls of which, and of the larger ducts, are much thickened and infiltrated with small round-cells. The epithelium lining the bile-ducts is, in most places, gone or breaking down. Many of the bile-ducts are completely occluded by the products of inflammation. There is also a little interstitial hepatitis, besides dilatation of the central vein and fatty degeneration of the liver-cells. The pancreas shows the lesions of interstitial pancreatitis, besides, in places, evidence of recent inflammation; no sign of carcinoma discovered. Mesenteric glands show only ordinary hyperplasia. Kidneys show the characteristic changes of chronic diffuse nephritis.

"This case may, then, be epitomized as one of primary carcinoma of the common bile-duct, causing obstruction to the flow of bile, general dilatation of the biliary passages and gall-bladder, jaundice, and secondary inflammation of the bile-ducts. The other lesions found were insignificant.

"It is hoped that in the discussion of this case some light may be thrown upon the interesting question of the etiology of primary carcinoma of the liver. Importance is given to this subject, when it is appreciated that the liver is fourth upon the list, as regards frequency, of the organs affected with cancer. To be sure, the large majority of these are secondary to new growths in other parts of the body; still, a considerable number of them cannot be shown to be so, and we are compelled to suppose them primary in the liver.

"The laws of evolution render it impossible to believe that a highly differentiated cell can change into one of entirely different character, and we are, therefore, compelled to believe carcinomata to originate from epithelial structures. In the liver two such epithelial structures are present, the liver-cells and the epithelium lining the bile-ducts. We must look to one or both of these, then, for the source of primary carcinomata in the liver. Formerly the liver-cell was thought to be to blame in nearly all cases, but latterly the epithelium of the bile-ducts has come to be looked upon as the more common source of the neoplasm. This latter view is strengthened by our knowledge of the development of the liver, if we believe, with Cohnheim,[1] in the origin of tumors from embryonic

[5] Durand-Fardel's patient was an old woman, eighty-one years of age, who apparently died of senility, the tumor having given no symptoms whatever.

[1] Cohnheim: Vorlesungen ueber allgemeine Pathologie. 2 Aufl. Leipzig, 1882, i., p. 723.

cells arrested in development, for all the epithelial structures of the liver have a common source—the epithelium of the embryonic bile-ducts. If we suppose some of these cells to be hindered in their evolution and to remain for a time inactive, later to take on an abnormal activity, we have at least a plausible explanation of the origin of primary carcinoma of the liver from the bile-ducts. The careful study of cases of primary cancer of the liver by Naunyn,[1] Waldeyer[2] and Weigert,[3] has lent much weight to this theory, almost amounting to proof. The case presented this evening, as well as the seven collected from the literature, seem to me to add evidence in favor of this idea, since they prove indisputably that carcinoma may originate from the gall-ducts outside the liver; and if this is possible outside the liver, why not equally well within it?"

Dr. Ira Van Gieson presented specimens illustrating

PRIMARY CARCINOMA OF THE COMMON GALL-DUCT, ENCROACHING ON THE PYLORUS AND LIVER.

"The specimen was taken from a woman, fifty years of age, who for twenty years had had fits of vomiting with intense epigastric pain. She was in the hospital but three weeks, and died deeply jaundiced, with symptoms of peritonitis.

"At the autopsy the wall of the common bile-duct was found to be uniformly thickened by a zone of rather dense white tissue, which also involved slightly the surrounding connective tissue, and a contiguous portion of the musculosa of the duodenum and pylorus. The latter contained in its musculosa a dense white nodule, 2 ctm. in diameter, which was not directly connected with the thickened duct. The thickened duct at its bifurcation into the hepatic ducts measured about two centimetres. Each of the hepatic ducts was about one and one-fourth centimetre in diameter. The thickening disappeared as the common duct entered the duodenum. Just before entering the liver each hepatic duct was adherent to the organ by a dense whitish zone growing into the liver. The enlarged and somewhat thickened gall-bladder contained about thirty variously sized, smooth, white-facetted gall-stones, and was adherent to the liver. Just above the gall-bladder the right lobe contained a hard, white nodule, 3 ctm. in diameter, not connected with the tubular mass surrounding the common duct and its branches. The liver also contained a number of rather small, scattered pus-cavities, the result of a suppurative inflammation about the gall-ducts. The intestines were loosely matted together and the abdominal cavity contained serum and flocculi of fibrin. There was nothing noteworthy about the other organs except that the kidneys were bile-stained.

"*Microscopical Examination.*—A large portion of the mass surrounding the gall-duct and its branches was composed of richly cellular connective tissue, in which were rather large acini lined with cylindrical epithelium. The nodules in the pylorus and in the liver were similar in structure. The pancreas and its duct were normal.

"Anatomical diagnosis was glandular carcinoma, primary in the gall-duct, and spreading thence to the liver and pylorus."

Dr. G. C. Freeborn presented a specimen illustrating

CARCINOMA OF BILE-DUCT AND PANCREAS, WITH CYST OF THE HEAD OF THE PANCREAS.

"The patient, a female, aged fifty-five, was admitted into the New York Cancer Hospital in September, 1888. Her history, taken from the records of the hospital, is as follows: She has always taken alcohol in moderate quantities and for the past three years has had considerable pain in the gastric region and attacks of vomiting, especially after eating. The heart-sounds were rapid, but no murmur was detected over the apex; a soft blowing murmur was detected over the pulmonary artery. At the junction of the epigastric with the right hypogastric regions, and at the lower part of the epigastric and umbilical regions, there is a mass approximating the size of an adult fist. This mass extends more below the umbilicus than above, and elevates the region about half an inch above the surface. It is hard to the touch and is immovable. Deep pressure causes no pain. The pulse is 106° F. The tongue is reddened. The patient is very anæmic. The stomach was washed out some fifteen times and no traces of hydrochloric acid were found.

"On November 18th a diarrhœa set in which was hard to control. From this time the patient grew weaker, and died in the first week of January. The clinical diagnosis of carcinoma of the stomach was made.

"*Autopsy.*—The right lung was normal; the left was œdematous and adherent at its apex. The heart showed some fatty degeneration of the muscle. The capsule of the left kidney was adherent and the cortical substance thickened; the right kidney was small but presented no marked lesions. The liver and spleen were normal.

"There were a few scattered ulcers in the rectum and descending colon. The head of the pancreas was embedded in a dense mass of tissue. The pyloric end of the stomach, as well as the descending and transverse portions of the duodenum, were adherent to this mass. Upon cutting into the mass a cyst which occupied the head of the pancreas was opened into, and found empty. In the anterior wall of the cyst two openings were found, one of which communicated with the ascending portion of the duodenum, the other with the transverse portion. The superior and anterior surface of the cyst was also adherent to the abdominal wall. The cavity of the cyst was irregular in shape and seemed to be limited to the head of the pancreas. No trace of the common duct could be found. The stomach was normal.

"*Microscopical Examination.*—The tail of the pancreas was normal. The walls of the cyst, except the anterior, were found to be made up of carcinoma with a small amount of pancreas tissue. The anterior wall was found to be made up of intestinal tissue infiltrated with a new growth of carcinoma."

Dr. T. M. Prudden said that it was well worth while bringing these three specimens together, for, while cancer of the liver with extensive involvement of the organ was commonly enough met with at autopsies, it was very rare to see a collection of cases, such as this, in which the lesions were in such an early stage. He was glad that Dr. Ely had stated his views concerning the origin of cancer of the liver, and his theory, if accepted, would simplify the question very much. It has been said that the presence of cylindrical cells in carcinoma of the liver shows that the tumor is from the gall-ducts, and if cylindrical cells are not found that it is a tumor of the liver proper. This is not correct, however, as the epithelium of the gall-duct is not composed entirely of cylindrical cells. The specimen presented by Dr. Freeborn would ordinarily be regarded as one of primary cancer of the pancreas, but taken in connection with the other specimens shown it could rightly be considered as occurring by extension from the bile-duct.

Dr. Van Gieson thought that the specimen presented by Dr. Freeborn was one of considerable importance, because it resembled other cystic forms of pancreatic disease, such as result from hemorrhagic pancreatitis. When death has taken place in an early stage of hemorrhagic pancreatitis we often find the lesion surrounded by zones of pancreatic tissue. But when the disease has existed for a longer period, it is found that the ascending peritonitis has resulted in the production of a wall incapsulating the pancreas. The tumor then becomes amenable to surgical treatment, and successful cases of removal have been reported by Gussenbauer and Thiersch.

[1] Naunyn, B.: Ueber die Entwickelung der Leberkrebse, Reichert u. DuBois-Raymond's Archiv, 1866, p. 717.
[2] Waldeyer: Die Entwickelung der Carcinome, Virchow's Archiv, lv. (1872), p. 67.
[3] Weigert, C.: Ueber primäres Lebercarcinom, Virchow's Archiv, lxvii. (1876), p. 500.

The intestines, matted together by the peritonitis and forming a wall around the pancreas, are very likely to be perforated, and sometimes the pancreas escapes in this way from the newly formed capsule. Rokitansky has reported such a case, and Chiari relates an instance in which no less than fifteen apertures were found in the wall surrounding the cyst.

Dr. Grauer reported a case that he had seen in Weigert's laboratory, Frankfort, of primary cancer of the gall-bladder, with secondary growths along the ducts and extending into the liver. He noticed that the gall-bladder was full of gall-stones, and Weigert told him that in his experience these concretions were always present in cases of primary cancer of the gall-bladder.

Dr. Freeborn called attention to

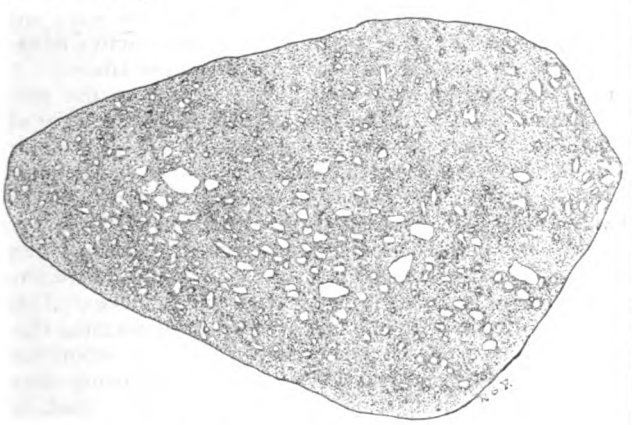
A NEW LAMP FOR ILLUMINATING THE FIELD OF THE MICROSCOPE,

devised by Dr. Koch. It consisted of an oil lamp with an ordinary argand burner. Fitting over the chimney was a sheet-iron shade in which were two apertures for the insertion of solid glass rods. One of these rods was curved so as to terminate beneath the stage of a microscope. The light from the burner was conveyed along this rod, and, after passing through a disk of blue glass to cut off the yellow rays, furnished a brilliant illumination for the examination of objects by transmitted light. The other rod was shaped so as to throw a light above the object when it was desired to examine it by direct illumination.

Dr. R. G. Freeman presented a specimen showing

MULTIPLE CAVITIES IN THE LIVER FROM POST-MORTEM DECOMPOSITION.

"This specimen is from a Polish woman, aged thirty, who died at Bellevue Hospital, when eight months pregnant, from rupture of the uterus. The autopsy was made by Dr. Prudden, through whose courtesy I am able to present the specimen.



"*Autopsy*, November 11, 1888, thirty-nine hours after death. Body fairly nourished; decomposition advanced. Liver full of small cavities, one to three millimetres in diameter; these cavities showed no special distribution along vessels, nor were they more numerous in one part of the organ than another; they were for the most part elongated, closed cavities.

"No cavities of this sort were found in the other organs. The liver was preserved throughout in alcohol. Microscopic examination showed the cavities to be surrounded by no membrane, nor was there any cell-infiltration in the surrounding liver-tissue. The edges of these cavities were in some cases ragged, in others smooth; some of the cavities contained a granular substance; in the vicinity of the cavities, as a rule, the nuclei did not stain. The bacteriological investigation was begun with the Grour stain, but staining with the aqueous solution of fuchsine gave much better results. Groups of large, stout bacilli were found here and there, while between the lobules throughout the liver occasional bacilli could be seen. In places the hepatic artery was filled by a great mass of these bacilli; many were also seen in the portal veins.

"Dr. Prudden tried to get cultures in gelatine from the liver, but no growth of micro-organisms took place.

"I have found no case similar to this reported. Through the kindness of Dr. Delafield, however, I am able to refer to two very similar cases observed by him, the material of which I have worked over and compared with that of Dr. Prudden's case. The first of these died of typhoid fever with perforation and peritonitis.

"*Autopsy*.—Body not well preserved. Liver showed multiple cavities, which varied in size from microscopic proportion to 3 mm. The liver was hardened in Müller's fluid.

"The second case died after several attacks of unconsciousness, with cyanosis.

"*Autopsy* in eight hours. Kidneys: Suppurative nephritis; no bacilli found. Liver: Studded with small whitish nodules, of the size of a pin's head, in some of which are cavities. The liver was hardened in Müller's fluid. The microscopic examination of these two cases showed practically the same condition as in Dr. Prudden's case. The white nodules mentioned in the second case were areas of intense bacterial invasion, and in which the nuclei did not stain. The same large stout bacilli were present in great numbers.

"These cavities, then, since there is no evidence of inflammatory change in the liver, are probably a post-mortem change due to the introduction through the circulation of putrefactive bacilli and the generation of gas by them; it is interesting, however, to note that in one case the autopsy was performed eight hours after death, during the winter months. The possibility of bacterial invasion during the preservation in Müller's fluid was obviated in the last case, where the liver was put directly in alcohol. This case has been thought worthy of presentation to the Society because the condition of the organ simulates a lesion."

Dr. Prudden said that cultures from this case were attempted on gelatine only. Nothing grew, but possibly better success might have attended trials in other media.

Dr. William P. Northrup presented some specimens showing

MILIARY GUMMATA OF THE LUNGS, LIVER, SPLEEN, KIDNEYS, AND LYMPHATICS IN A CHILD NINE MONTHS OF AGE.

A male child, aged nine months, was returned to the New York Foundling Asylum from the Out-door Department, suffering from moderate conjunctivitis, and, in addition, "seemed sick;" it had a temperature of 102½° F., and slight increase in rapidity of respiration. It died thirty-six hours after entrance. There was no eruption, and no diagnosis was made.

*Autopsy*, fourteen hours after death. Brain: Normal. Pharynx and larynx: Catarrhal inflammation, with moderate swelling of the mucous membrane, and superficial ulcers at the base of the tongue and between the arytenoid cartilages. Lungs: Bronchial and tracheal glands enlarged and cheesy. There were no adhesions. On the surface of the lungs were three to five miliary bodies like tubercles. On section four to six pea-sized cavities, with thick walls and with branching processes, were found. No hepatization. Heart: Normal. Liver: Thickly studded with round, opaque yellow bodies two to five millimetres in diameter. These on section showed a granular centre surrounded by a pellucid zone. There were a few bile-stained points in the centre, obviously the openings of gall-ducts. The whole organ was the seat of extensive fatty infiltration. The cœliac lymph-nodules were markedly enlarged and mostly cheesy. Spleen: Firm, dark, moderately enlarged; ten to twelve miliary, opaque white bodies were found on the surface and on section. Stomach: Normal. Intestines: Contents, bile-stained mucus.

Microscopic examination showed the nodules to be

characteristic gummata of the lungs, liver, spleen, and kidneys, and of the lymphatics at the root of the lungs and at the cœliac axis.

CANCER OF THE UTERUS, WITH INVOLVEMENT OF THE OVARIES.

Dr. H. J. Boldt presented two cancerous uteri, obtained by vaginal hysterectomy. In the first case the patient had suffered from hemorrhages only a short time; in the second case, however, the disease had existed, judging from the symptoms, fully six months, and the cancer involved the body of the uterus. In this case the interesting feature was that the ovaries were simultaneously involved. This possibility existing in cases in which the body is diseased showed the importance of always removing the appendages, although formerly it had not been the speaker's habit to do so unless it could be done without trouble. The lesson learned in this instance, however, would lead him always to follow this procedure in the future.

Dr. Boldt presented a third specimen, showing a

SARCOMA OF THE OVARY,

removed on the previous day. The main symptoms present were menorrhagia and pain on the affected side.

A fourth specimen was one of

OVARIAN CYSTOMA,

with beginning malignant changes in the thickened wall of the tumor near its origin. It had existed over two years and had attained a large size. It showed the importance of operating early in all cases of ovarian tumor. All the patients from whom these specimens were removed were doing well.

Dr. R. H. Sayre presented a knee-joint, removed by amputation, showing lesions of

ACUTE OSTEOMYELITIS FOLLOWING TUBERCULAR ARTHRITIS OF LONG STANDING.

The patient had had knee-joint disease for five years, the trouble coming on after an attack of measles. Last July he was seen by Dr. Sayre, and his knee was at that time flexed and swollen. Abscesses formed and were opened. The patient went to the country, contrary to advice, without having proper protection for his knee, and when he returned there was more marked trouble in the knee, and he had a high temperature and other constitutional symptoms. The leg was amputated in the upper third of the thigh. The medullary canal was scraped out sufficiently, as it was supposed, but the patient now has a return of the high temperature, and there is evident extension of the disease in the bone.

Dr. Frank Grauer presented some specimens removed at autopsy from the body of a young man, showing

MALIGNANT ENDOCARDITIS

affecting the mitral, aortic, and tricuspid valves. There were infarctions in the spleen and small miliary abscesses in the kidneys and liver. In the left lateral ventricle of the brain a large hemorrhage had occurred which had extended both anteriorly and posteriorly. Throughout the brain there were also small extravasations and abscesses. Cultures made from the lesions in the kidney showed the presence of a micro-organism supposed to be a streptococcus. In the small intestine, in the neighborhood of the ileo-cæcal valve, were found small nodules thought to be tubercles, and a little above this point was another collection of tubercles. These were the only tubercles found anywhere in the body.

Dr. Grauer also presented a specimen showing

TYPHOID ULCERATION OF THE INTESTINE.

The Society then went into executive session.

---

The Solubility of Quinine is said to be greatly increased by the addition of a little antipyrine.

# Correspondence.

## PROFESSIONAL OVERCROWDING AND THE SINGLE TAX.

To the Editor of The Medical Record.

Sir: In The Record, for June 22d, on page 700, is an item stating that a Western physician recently read a paper in which he showed that overcrowding in the profession would be prevented were the single tax on land values, as advocated by Henry George, in operation.

As the connection between the land-value tax and overcrowding in the ranks of the medical profession may not seem at all obvious to those whose only knowledge of the theories of Henry George is that obtained through the distorting medium of the daily press, and as any plan for making the struggle for existence more bearable should be received with attention by those to whom it is addressed, and especially by the more recent additions to the ranks, it may not be out of place for one of the many physicians who are earnestly laboring to bring about a realization of Henry George's plans, to try to show where the connection lies.

When we contemplate human society from the economic point of view, we find that the struggle for existence centres around the strife for the material things with which we gratify our necessities and desires, and which collecively we call wealth. Now, nature yields wealth to one thing only, and that is labor. But labor alone is powerless. It must have a field of operation; it must have the raw material to work upon; it must have opportunity. And the opportunity for labor is land.

No matter what particular kind of wealth a man may produce, directly, or indirectly, he must go for his materials to the great, and in the last resource the only, storehouse, the earth. (Here let me say, parenthetically, that physicians are, economically speaking, non-productive laborers. They belong in the same category as lawyers, actors, preachers, ballet-dancers, and the like, and are paid out of the wealth of the community, unlike productive laborers, whose wages consist of the fruits of their labor.)

But, if we allow land—the passive factor in the production of wealth—to become the absolute property of some, and there always a minority of the population (for in all countries, this included, the land is in the hands of the few, while the great mass is landless), it must necessarily follow that, as natural opportunities to labor are fenced in, those who are so unfortunate as to have been born outside the fence will be willing to pay to the owners of the fences a goodly price to be allowed inside. This premium, which is given in exchange, not for anything that the landholder has in his turn produced by labor, but simply for being granted the privilege of employing one's self on God-given opportunities, is called rent. And be it here noted, please, that in economics the term "rent" applies only to natural opportunities, and never to houses, or to anything made by the hand of man.

While population is sparse the monopolization by the few of the rightful heritage of all produces but little effect. But as soon as all the land is "owned" (which by no means implies that it is *used*) then trouble begins. The increasing pressure of population continually increases the premium which the landless have to pay for access to natural opportunities for labor, and thus the landlords are enabled to appropriate a continually increasing share of the products of others' labor without further exertion than collecting the rent. And in countries like our own, where not only the land is fenced in, but the ocean is fenced out by a tariff wall, so that men are forbidden, unless they pay a fine, to make the most profitable exchange of the wealth they have produced, of course the impoverishment of the many to the enriching of the few goes on at accelerated speed.

(I have not got to the doctor yet, but I am gradually approaching him, and promise to produce him shortly.)

Well, the increasing pressure of the landless against the parchment fences, called title-deeds, forces men to look about them for employment less directly connected with land than the one they have been accustomed to. It drives men from the country to the cities, in the hope that the infinite diversity of desires which is to be found wherever there is a large population may afford employment. Hence the phenomenon at present complained of wherever land is made private property, of the congestion of population in large cities.

It explains perfectly what our State assessors have reported, namely, the enormous increase in the land values of towns and cities, and the falling off in the value of farm lands. This is due simply to the fluctuation of population. For land value, represented in ground rent, is determined solely by demand, created by density of population.

As men become removed further and further from the means of actually *producing* wealth, they naturally seek for the means of obtaining wealth from those who have produced it. I have said that, economically speaking, professional men are classed as unproductive workers. The community needs them, and willingly sets aside a certain portion of its wealth for their maintenance. Hence, as an (apparently) easy way of making a living, men crowd not only into the medical, but into nearly all professions, especially into those where the element of success is not so much actual knowing as the art of making people think you know.

The farmer's son, who sees his father and mother slaving from morning to night with an unpayable mortgage on the farm as his prospective inheritance, and then notes that the country doctor apparently does little else than drive about behind a pair of fast trotters, and in addition that he wears a long-tailed broadcloth coat every day of the week, does not, I know, reason in this way when he decides to go to the nearest town that has a medical college to become a doctor. But though they are not *his* reasons, yet they are *the* reasons. He is but the puppet irresistibly controlled by the laws of economics. He is but following the law that impels men to seek to gratify their desires with the least exertion; a law, of which it has been said that it is to political economy what the law of gravitation is to mechanics. I follow it, you follow it, we all follow it. Not because we are lazy, but because it is a natural law. We follow it for the same reason that a brook runs down hill, not up—because we *must*.

Well, now, my medical brother, who is perhaps wondering how a living is to be made by giving advice free to pauperized patients at a dispensary, you may ask, how is the single tax, the land-value tax, going to remedy matters? Pray listen, and think it well over in the solitude of your office hours, for the matter interests you.

Clearly the way to relieve the overcrowding in our profession, in all professions, and in the ranks of labor generally, is to undo the conditions which have caused the overcrowding, and which we have just traced.

Throw open natural opportunities. Tear down the fences that keep men from the element which is life itself—the land. And the way to do it, the practical way, the feasible way, the just way, the *only* way, is not by seizing the land and redistributing it, but by exacting from those who now or at any time may occupy it, the full ground rental value, and take nothing else. Take for the uses of the community only the value with which it, in its communal function, has endowed the soil, and to which it is therefore rightfully entitled, and cease confiscating, as is now the custom, the hard-earned wealth of the toilers. Put the tax on monopoly, and take it from labor. Where the full ground-rent is absorbed by the community in the form of a tax, what man could afford to hold land idle that another man might want to use? He would either have to use it himself, by farming on it, mining on it, building a house or factory on it, or putting it to any other useful purpose for which it was fitted, in order to get the amount of the tax out of it plus a profit, or he would have to stand aside and let the man who would work it occupy it.

In this way all natural opportunities would be forced into the freest, fullest use, and no man would be idle, unless he chose to be; the rent that each man paid would but represent the equal rights of all others to what he is monopolizing; and the earth, given as the heritage of God to all his children, and not to afavored few, would return to the people once more.

The spectacles that now meet our eye—of freezing in the midst of unused fuel, of starving in the midst of stores of food, of wretchedness generally while all the means for relieving it are spread by the prodigal hand of nature on every side—would no longer disgrace our boasted civilization.

To you, my recent graduate, thrown so lately from your Alma Mater into an unappreciative world, the problem of overcrowding in the profession will most pressingly present itself.

Think it over, as you haply trudge up and down foul tenement-house stairs, the emissary of some health board, ladling out diarrhœa mixtures to sickly infants who are being crowded off this fertile earth every year by the thousand, and yet, who are born with rights to life not inferior to those of the richest landlord's child in the city. Ask yourself, why all this herding together of human beings? why all this poverty, hunger, and dirt? Don't, in your plenitude of knowledge, be hasty in your judgment and say it is because the people are lazy, drunken, and vicious. I think you would be the same were you condemned to such surroundings. I am quite sure I would be.

Go back to your office and wait, day in day out, for the patient that does not appear. Why is it that you have such a hard time to get along? Are you too, perhaps, lazy, drunken, and vicious? Is it not rather because those who now demand your services are debarred by unjust social conditions from producing the wealth wherewith to pay you? For that you *are* needed in the world there is no doubt, else you would not be sent under the guise of charity to relieve the sick poor. Try, my friend, to bring about juster social conditions, conditions that will not condemn thousands of men to stand in enforced idleness in one of the most sparsely settled of countries, like our own; and so by raising others you too will rise. If we would relieve our own overcrowded profession we must begin not with ourselves, but by helping those still more crowded and overburdened to emerge into conditions of freedom, into a better, purer, and nobler life.

WALTER MENDELSON, M.D.

NEW YORK.

## THE SINGLE-TAX THEORY AND THE DOCTOR.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: I see in your valuable journal of June 22d a reference to the article on "Overcrowding in the Medical Profession," by Dr. Cornick, of Mascoutah, Ill., which appeared in the *Journal of the American Medical Association* some weeks ago.

That article was of most striking merit, and I only regret (for the sake of our profession) that you were unable to give any extended abstract or summary in your widely circulated journal.

As members of the *most* liberal profession, I feel that it is our duty to take careful note of the progress of the "new political economy," and of the vast changes in our social structure of which it is unquestionably the precursor. The proposition to leave, unhampered by restrictive taxation, all the products of our industrial forces in the possession of those who practically create them, and to meet the common needs by drawing for public revenue upon those values which are solely the result of a community's growth and common industry, viz., land values,

should receive, if nothing more, at least our cold intellectual assent, as a mere fiscal method that is perfectly simple, absolutely exact, conducive to political purity in assessment and collection, most equitable, and with none of the objectionable features in the present method.

To me its advantages are vastly greater and more far-reaching. This single-tax, in its death-blow to speculative land-holding, would really give our industrial forces easy and continuous access to those natural opportunities from which all wealth must primarily be produced.

The greatly augmented production that would ensue, not being drained away in economic rent (ground-rent), would necessarily follow such laws of distribution as would elevate our industrial classes to a plane of proper remuneration, steady employment, and, as a consequence, ample comfort. Dr. Cornick very clearly shows how the proper share of this increased wealth-production would rest finally with the watchers over the health of the community. This is our selfish interest in this reform—the increase of our incomes.

The destruction of speculative land-holding would have two tendencies (apparently at first sight diverse, but really analogous). In our cities it crowds our poorer classes into tenements, while abundant building-sites are held out of use on every hand. In preventing this, the reform will settle that evil problem, "the tenement-house question." Only physicians can realize the resulting benefits to health and happiness, the lowered mortality, the improved morality, the lessened temptations to intemperance and vice, that would result from a gradual transfer of our tenement populations to smaller family-homes of their own. In our rural districts families are separated and isolated, while vast tracts of unused land lie between them. Their lives are thus narrowed, hampered, and restricted, while they are deprived of many of the advantages of our advancing civilization that might readily be theirs. In destroying speculative land-holding, rural population would tend to at least healthful density; and social pleasures and neighborly co-operation (which make up more than half of life) would begin to brighten the dull tedium of isolated country-life.

These are a few of the social improvements that we may accurately and absolutely predict; and it is the appeal that these make to the better, unselfish sides of our natures that should most attract us.

You speak of "Henry George's land-tax theories," and as a physician I wish to protest. I am too proud of my profession to neglect the opportunity of claiming for it the initiative in the greatest movement of modern times. To the famous Quesnay, the Court Physician to Louis XVI., and the intimate friend and adviser of the great minister Turgot, belongs the honor of having first proposed an "impôt unique."

Yours fraternally,

DAVID DEBECK, M.D.,

*Assistant to Chair of Ophthalmology, Medical College of Ohio; Librarian Cincinnati Single-tax Club.*

## MEDICAL NOTES IN THE NORTHWEST.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It is supposed by many physicians in the East that the profession in the West has not kept up with the rapid material development of that section. Doubtless this is true with reference to certain parts of the country, but it cannot apply to the Northwest. In some respects they are in advance of many of the Eastern States. This is particularly true with reference to medical legislation and examination. Minnesota has an excellent and stringent law for regulating the practice of medicine. This law is embodied in eight sections, the two most important being as follows:

"Sec. 3. All persons hereafter commencing the practice of medicine and surgery, in any of its branches in this State, shall apply to said board for a license so to do, and such applicant, at the time and place designated by said board, or at the regular meeting of said board, shall submit to an examination in the following branches, to wit: Anatomy, Physiology, Chemistry, Histology, Materia Medica, Therapeutics, Preventive Medicines, Practice of Medicine, Surgery, Obstetrics, Diseases of Women and Children, Diseases of the Nervous System, Diseases of the Eye and Ear, Medical Jurisprudence, and such other branches as the board may deem advisable, and present evidence of having attended three courses of lectures of at least six months each; said board shall cause such examination to be both scientific and practical, but of sufficient severity to test the candidate's fitness to practise medicine and surgery. When desired, said examination may be conducted in the presence of the dean of any medical school or the president of any medical society of this State. After examination, said board shall grant a license to such applicant to practise medicine and surgery in the State of Minnesota; which said license can only be granted by the consent of not less than seven members of said board, and which said license shall be signed by the president and secretary of said board, and attested by the seal thereof. The fee of such examination shall be the sum of ten dollars, and shall be paid by the applicant to the treasurer of said board, to be applied by said board toward defraying the expenses thereof; and such board may refuse or revoke a license for unprofessional, dishonorable, or immoral conduct. In all cases of refusal or revocation the applicant may appeal to appointing power of said board.

"Sec. 6. Any person practising medicine or surgery within this State without first having obtained the license herein provided for, or contrary to the provisions of this act, shall be deemed guilty of a misdemeanor, and upon conviction shall be fined not less than fifty nor more than one hundred dollars, or by imprisonment in the county jail not less than ten nor more than ninety days, or both fines and imprisonment. Any person shall be regarded as practising within the meaning of this act who shall append the letters 'M.D.' or 'M.B.' to his or her name, for a fee prescribe, direct, or recommend for the use of any person any drug or medicine, or other agency for the treatment, care, or relief of any wound, fracture, or bodily injury, infirmity, or disease; provided, however, this act shall not apply to dentists. Justices of the peace and the respective municipal courts shall have jurisdiction over violations of the provisions of this act. It shall be the duty of the respective county attorneys to prosecute violations of this act."

The examinations for license to practise are conducted with great impartiality, the applicants being known to the examiners only by the numbers on their papers. Any applicant for examination, who is a graduate of over five years' standing before making application, is considered an "old practitioner," while an applicant who is a graduate of less than five years is considered a "recent graduate." The latter class are required to attain a rather higher percentage in order to pass than the former. If the Board is somewhat uncertain about passing a candidate, a supplementary oral examination may be given upon those subjects in which the applicant has failed to pass an entirely satisfactory examination. Any applicant failing to pass the examination may present himself at any subsequent regular meeting of the Board and receive another examination. The Examining Board consists of nine members, two of which must be homœopathic physicians. No member of any college or university having a medical department is eligible to serve upon this Board. The actual operation of the Minnesota law has been exceedingly good. Since July 1, 1887, when the law first went into effect, 123 candidates have come up for examination, of whom 79 have passed. This law is a great step toward the suppression of quackery. The Secretary of the Board tells me that within the past three months 9 quacks have been driven from the State, 17 compelled to stop practice, and 20 to come up for examination. It is needless to say that

there has been much opposition to this law, which has resulted in several legal contests, but its constitutionality has been upheld by five different decisions of the courts. Montana passed a similar law last winter. In Wisconsin and Kansas the Minnesota law was killed by a small majority. Iowa, Missouri, West Virginia, and Dakota have the Illinois law in force. This law requires a diploma the recognition of which is based on the will of the Board, or an examination of those not possessing such a diploma.

Several small medical colleges in St. Paul and Minneapolis have recently consolidated into the medical department of the University of Minnesota. This institution requires a preliminary examination and a three years' graded course, so that the change has been a good one for higher medical education.

There seems to be a strong tendency toward specialism in the West. It is a question whether a halt will not have to be called soon in this direction. The lucrative returns and regular hours of some noted specialists have tempted many to abandon general practice. After all, however, the legitimate field of many specialties is comparatively narrow, in spite of the ever present "reflex," and if they become overcrowded, the art and reputation of medicine must suffer. The tone of the profession in St. Paul is exceedingly high, as anyone can testify who has had the pleasure of meeting many of its members.

HENRY DWIGHT CHAPIN, M.D.

ST. PAUL, MINN., July 24, 1889.

## THE CAUSE OF RICKETS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Some months ago, in a letter which you thought worthy of publication, I made the suggestion that the attention of the profession might well be directed to the consideration of the frequency and the cause of rickets as it occurs in the United States.

It is with great regret that I find there is a tendency, if I may judge by the paper contributed by Dr. Irving Snow, of Buffalo, on this subject, that more trouble is taken to explain the views of others than to give the simple results of actual personal observation of the disease as met with in practice. What we require is a careful clinical report of the facts of each case, without any theory as to causation, for there is no theory that satisfies all conditions. There is no evidence in England that want of proper food is a cause of rickets, for we find the disease quite common among the well-to-do classes in this country.

It is absolutely necessary for anyone who undertakes to investigate the question of causation to start with a perfectly free mind and to trust to nothing but actual observation.

There is but little to be gained by stating the opinions of the past in regard to this matter, for the most singular and irreconcilable differences exist. If we could obtain, in the first place, some accurate idea of the frequency of rickets in the different parts of the United States, it would be most interesting and valuable, and I venture to hope that you will use your influence in obtaining such a report. I am, obediently yours,

ROBERT LEE.

LONDON, June 24, 1889.

CHANGE OF NAME.—The name of the *Annales Médico-chirurgicales*, of Paris, has been lengthened to the *Annales de Thérapeutique Médico-chirurgicales*. We wish our esteemed contemporary a long and prosperous existence under its new title.

# New Instruments.

## RETINOSCOPE, PUPILLOMETER, AND STRABISMOMETER COMBINED.

BY JOHN E. WEEKS, M.D.,

NEW YORK.

A LONDON maker of optical instruments has introduced to the medical profession an instrument combining a retinoscope and pupillometer in the compact form represented in Fig. 2. Desiring to have a strabismometer always conveniently at hand, I have copied the frame of the London instrument and caused an instrument to be made combining a retinoscope, pupillometer, and strabismometer in the same compass.

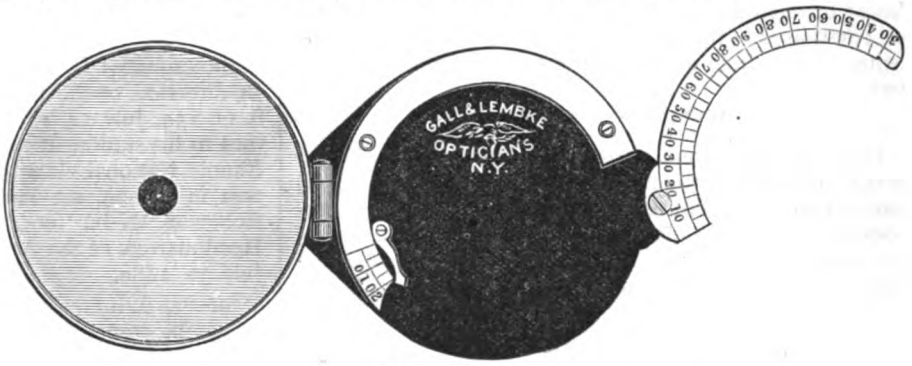


FIG. 1.—Open.

The retinoscope consists of a plane perforated mirror with a diameter of 40 mm. This I consider to be the best form of mirror for retinoscopy, as the illumination obtained is very good and the range through which it can be satisfactorily used is greater than with the concave mirror. The pupillometer consists, as represented in Fig. 2, of a perforated metal disk. The perforations are sixteen in number, with diameters ranging from one to ten millimetres. This disk is fastened securely to the back of the instrument.

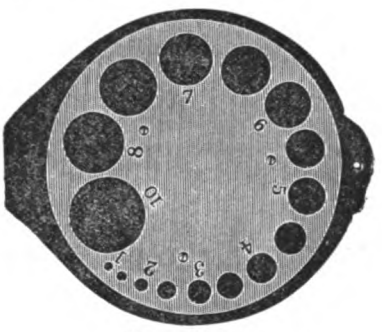

FIG. 2.—Closed.

The movement of any given point on the surface of the globe of the eye is about a central point, more or less fixed, and the excursion of a point on the cornea which serves to measure the degree of deviation in a squinting eye is, in the vast majority of cases, on a horizontal plane, and is virtually the movement of a point through the arc of a circle whose radius is about 13.2 mm. in the adult eye.

Because of the existing conditions above mentioned, ophthalmologists recognize the desirability of measuring the amount of strabismus in degrees. This cannot be accomplished by the strabismometer of Lawrence or the binocular instrument of Galezowski, as these instruments are designed for linear measurement, being marked in lines or millimetres not representing the tangential measurement of angles. The measurement of squint in degrees of a circle is made by use of the arc of the perimeter, or by the ophthalmotropometer of Snellin; but the use of these instruments requires more time than can

usually be given for such a purpose. To overcome this difficulty I have devised a strabismometer which consists of the arc of a circle with a radius of 14 mm., marked in degrees, so combined with retinoscope and pupillometer that the whole when closed corresponds in size to Figure 2, and can be carried in the vest-pocket.

As seen in Fig. 3, the strabismometer represents one hundred and fifty degrees of the circumference of a circle, and is marked as represented. When in position the antero-posterior axis of the globe, passing through the centre of the pupil, cuts the strabismometer at ninety degrees; the diameter of the circle of the strabismometer at right angles with the point marked ninety minutes, if continued through the globe, would pass through the centre of rotation of the globe, this centre being also the centre of the circle of which the strabismometer forms a part.

DIRECTIONS FOR USING.

Place the strabismometer over the eye to be measured so that its upper surface falls a very little below the horizontal plane of the centre of the pupil, the antero-posterior axis of the globe passing through the centre of the pupil, cutting the arc of the strabismometer at ninety degrees, when the eye fixes a point on the median line

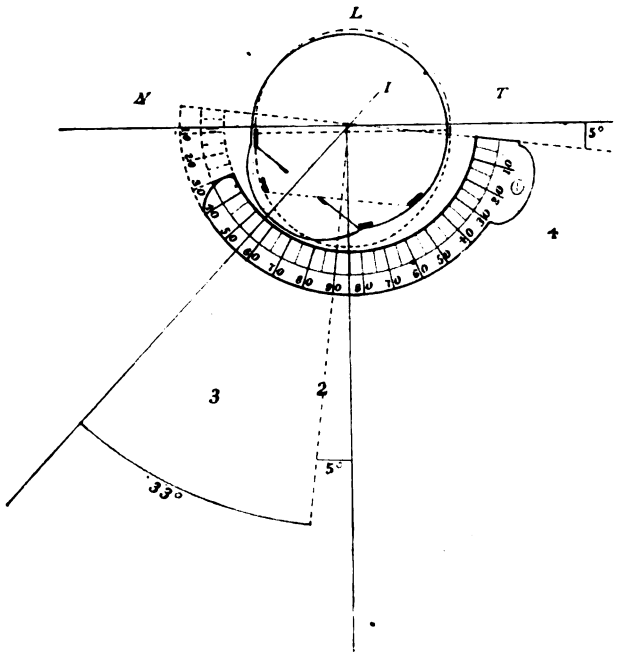

FIG. 3.—1. Centre of rotation. 2. Direction of optical axis when converged for 14 inches in front of eye. 3. Angle of deviation in a supposed case. 4. Strabismometer in position. *T.* Temporal side. *N.* Nasal side.

and on the horizontal plane at about fourteen inches distance. This may be obtained by covering the eye that usually fixes. After having obtained this position, remove the covering from the eye that ordinarily fixes, cause it to fix the point at fourteen inches, and, by following the movement of the deviating eye by movement of the observer's head, read off the degrees of squint from the graduated arc (Fig. 3).

All measurements of strabismus are approximate. This instrument, however, affords a strabismometer which gives sufficiently accurate results and is easy of application. The measurement of strabismus where the vision is eccentric can be best made by a binocular instrument, which I shall probably soon present.

---

MONDEVILLE'S ANATOMY.—Dr. Pagel, of the Royal Library of Berlin, announces that he has found there the manuscript in Latin of a work on anatomy, written in 1304 by Henri de Mondeville, surgeon to Philip the Handsome, of France.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 28, to August 3, 1889.*

HALL, WILLIAM R., Captain and Assistant Surgeon. Granted leave of absence for ten days. Par. 5, S. O. 80, Headquarters Department of Dakota, July 27, 1889.

ROBINSON, SAMUEL Q., Captain and Assistant Surgeon. The leave of absence by Par. 11, S. O. 165, from these headquarters, is hereby extended ten days. Par. 8, S. O. 172, Headquarters Division of the Atlantic, July 30, 1889.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. By direction of the Secretary of War, so much of Par. 1, S. O. 159, July 12, 1889, A. G. O., as directs him to return to his station at the close of the encampment of the Illinois National Guard, is amended to direct him to report in person, not later than August 20, 1889, at Fort Robinson, Neb., for duty at that place. S. O. 174, Headquarters of the Army, A. G. O., Washington, D. C., July 30, 1889.

SHAUS, LOUIS M., Captain and Assistant Surgeon. Is hereby granted leave of absence for twenty days, on surgeon's certificate of disability. Par. 2, S. O. 173, Headquarters Division of the Atlantic, August 1, 1883.

HARRIS, H. S. T., First Lieutenant and Assistant Surgeon. By Par. 9, S. O. 176, A. G. O., August 1, 1889, the leave of absence granted in S. O. 140, A. G. O., June 18, is further extended two months.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 3, 1889.*

BRYANT, P. H., Assistant Surgeon. Ordered to temporary duty on iron-clads, Richmond, Va.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 3, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 37 | 13 |
| Scarlet fever | 29 | 2 |
| Cerebro-spinal meningitis | 3 | 3 |
| Measles | 31 | 1 |
| Diphtheria | 74 | 22 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

FOR PLUGGING THE NARES TO CONTROL EPISTAXIS.—Dr. Juan W. McCoy, of this city, sends a description of a device for controlling nasal hemorrhage not susceptible of control by the ordinary means. It consists of a flexible tube provided at one end with a stopcock, and surrounded at the other end by a bag of soft rubber. The bag is long enough to reach back of the posterior nares, while the other end projects from the anterior opening of the nostril. In the part of the tube surrounded by the bag are several perforations through which water may be forced. The tube is introduced and then the stopcock is opened, and hot or cold water is forced into the bag until the latter is well inflated so as to exert an even pressure, and by its expansion at either projecting end to effectually plug the anterior and posterior nares. Now the stopcock is closed, and the instrument may be left in the nose as long as necessary. Inflation may be effected by means of an ordinary Davidson syringe.

## Original Articles.

### SOME RECENT SURGICAL CASES.

EIGHT CASES OF SUPRA-PUBIC CYSTOTOMY; ONE CASE OF SIMULTANEOUS DELIGATION OF LEFT CAROTID AND LEFT SUBCLAVIAN ARTERIES FOR AORTIC ANEURISM; TWO CASES OF DELIGATION OF EXTERNAL CAROTID ARTERY—ONE DOUBLE, ONE SINGLE; THREE CASES OF AMPUTATIONS; FOUR CASES OF EXCISION OF KNEE.

BY JOHN A. WYETH, M.D.,

PROFESSOR OF SURGERY AT THE NEW YORK POLYCLINIC.

SUPRA-PUBIC CYSTOTOMY.—Of the 8 cases of cystotomy herewith reported 3 were for removal of tumors; 2 were for the removal of calculi, and in one of these a tumor of the prostate was also removed; 1 was for removal of foreign body; 1 was for relief of chronic cystitis; 1 was for cure of vesical fistula.

The operations occurred within a year from May, 1889. All recovered. One case of cancer, greatly relieved and improved by the removal of the mass, suffered a recurrence in the bladder and lymphatics of abdomen, and died six months later.

The cases of stone and foreign body were cured. In one case of stone an enlarged middle lobe of the prostate was removed, enabling the patient to void his urine without a catheter, which he had not been able to do for many years. A third tumor case was relieved of the distressing bladder symptoms, and a fourth case, now under treatment, will without doubt be cured.

The case of cystitis was discharged cured after drainage and irrigation through the wound for three weeks, and the case of fistula was cured easily and promptly.

CASE I. *Supra-pubic Cystotomy—Tumor of Bladder—Epithelioma—Recovery.*—X——, male, aged forty, United States, unmarried. First seen July 7, 1888. Specific urethritis twelve years ago, never entirely cured. Discharge at times until two years back, when the stream of water became smaller and smaller until complete retention ensued. Sounds were employed. Seven months since, marked hæmaturia, with chills and high temperatures. Pain in lower part of abdomen. Has alcohol and tobacco habits. Syphilis excluded. Urine pale,acid, albumen ten per cent. Patient's condition not good, appetite fair, bowels regular. No family history of interest.

July 18, 1888.—Ether. Supra-pubic cystotomy. On entering the bladder I discovered a soft, spongy tumor, mushroom in shape, the pedicle attached near the neck of the bladder, the parasol-like expansion of the growth filling about half of the cavity. It was friable, broke down under the finger, bleeding considerably. It was easily removed, the attachment gouged out with a sharp spoon, bladder irrigated with Thiersch's solution, Trendelenberg's T-rubber drainage-tube inserted, wound packed with iodoform gauze.

July 22d (fourth day).—Temperature normal, no ill effects of operation. Patient improved as to comfort. Bladder washed out with Thiersch's solution through T-tube every four hours since operation.

Eighth day, tube removed; ninth day, temperature 103° F.; tenth day, 104° F.

Sixteenth day, urine ceased to escape through wound. By August 14th had healed entirely.

Sections under microscope showed mass to be carcinoma. Discharged August 15th, greatly improved. Neoplasm showed signs of recurrence in October, and patient died in December, 1888, from sepsis and exhaustion.

CASE II. *Tumor of Bladder—Supra-pubic Cystotomy—Recovery.*—J. P. L——, male, aged thirty-six, United States. First seen July. 1888.

September, 1883, patient had renal colic, which left him with frequent micturition and pains in left lumbar region for eighteen months, when a second severe attack ensued. Since then attacks have occurred at more frequent intervals, lasting from a few hours to several days.

During the paroxysms urination very painful and urine bloody.

Personal history good. Father died during paroxysm of renal colic, about sixty-four years of age.

Patient in good condition. Urine pale, acid, 1.018; trace of albumen, pus-cells, and epithelia. Seen in consultation by Drs. Sands and Gerster. Operation advised. Small elevation on floor of trigonum made out by cystoscopic examination.

July 20th.—Supra-pubic cystotomy. A small sessile tumor, about three-quarters of an inch across its base, and elevated about a quarter of an inch above the floor of the bladder, was found occupying the left side of the trigonum vesicæ, half-way between the left ureter's mouth and the urethral orifice. It was firm to the touch. With the sharp spoon it was scraped out. Hemorrhage arrested by hot Thiersch solution; T-shaped drainage-tube, iodoform gauze packing.

July 21st.—Patient comfortable; temperature 100° F.; bladder irrigated every three hours with Thiersch.

July 26th.—Tube removed; temperature normal.

August 7th (eighteenth day).—Wound in bladder closed.

August 15th.—Temperature 102° F., cause not known; quinia sulph., gr. v., twice a day.

August 29th.—Discharged cured.

This patient is still under observation. His bladder symptoms are relieved, but he has had three attacks of intense renal pain in the last six months. There is evidently either tumor of the kidney or renal calculus. I have advised exploration, and he has consented.

CASE III. *Supra-pubic Cystotomy for Tumor of the Urethra and Bladder.*—F. G——, female, aged twenty, servant, first seen in 1888. Family history of no interest. Patient complained of inability to pass water. On introduction of catheter, which went in easily, bladder was emptied. Examination per vaginam revealed almost complete occlusion of this canal by adhesion three inches from vulva; hymen present. Suspecting spasm of constrictor urethræ muscle, caused by the vaginal stricture, I stretched the urethra and removed the vaginal obstruction. The patient's condition was not improved. Left without catheterization the bladder would fill until it was greatly distended and then overflow. With the cystoscope I noticed what seemed to be a fold of the mucous membrane of the bladder which was pouched above the internal urethral orifice.

March 26, 1889.—Supra-pubic cystotomy. A small polypus was found filling up the urethral opening and projecting slightly into the bladder. With my little finger this was pushed outward through the urethra, and extracted by the external meatus. It was attached by a long filamentous pedicle to the urethra, growing backward into the bladder. As the urine accumulated, it was evi-

dently driven into the urethra, plugging it and causing probably spasm of the constrictor muscle. The wound in the wall of the bladder was closed at once with catgut sutures, and the wound above this packed with iodoform gauze. A soft catheter was fastened in the urethra and bladder. The patient recovered without any unfavorable symptoms. The wound in the bladder united well without ever leaking. She still has some difficulty in expelling the water, due, I believe, to weakness of the bladder-muscle from chronic over-distention, but this will, without doubt, be relieved by proper treatment.

CASE IV. *Supra-pubic Cystotomy for Vesical Calculus and Tumor of the Prostate—Recovery.*—M. B. M.——, male, aged sixty-seven, United States, came under observation August 28, 1888. Gave history of stricture of urethra of long duration. For seventeen years had drawn urine by catheterization. Has had various attacks of cystitis. Typhoid fever in 1885. Gives history of rheumatism and malaria. Excessive tobacco habit. Has been treated for cystitis by vesical irrigation.

August 28th.—Condition fair; urine, 1.020, amber, alkaline, pus-cells, triple phosphates, trace of albumen.

September 4, 1888.—Ether; operation. Phosphatic calculus, one inch and a quarter in longest measurement, removed. An enlarged third lobe of the prostate projected from the floor of the bladder in such a manner as to close the urethral orifice. Removed with sharp spoon. T-drainage-tube through wound, iodoform gauze. Patient had no rise of temperature. On sixth day tube removed; on fifteenth day wound had closed.

October 1st.—Discharged cured. Could pass water without catheter, although bladder power is much crippled from long over-distention and disuse.

CASE V. *Supra-pubic Cystotomy for Vesical Calculus—Recovery.*—September 24, 1888; Abraham L——, aged forty-six, Russian. About three years ago patient began to have frequent and painful micturition. These symptoms gradually increased. No hæmaturia. Has had hæmorrhoids at intervals for twenty years. History otherwise negative. General condition fair; temperature, 98° F.; urine, 1.020, acid, albumen trace, oxalate lime crystals, and phosphates. Exploration with sounds demonstrates presence of large calculus.

September 28th.—Operation. Ether. Flat, elliptical stone removed, measuring $2\frac{1}{2} \times 1\frac{1}{2} \times \frac{3}{4}$ inches. T-tube and iodoform gauze-dressing.

October 3d.—Temperature not over 100° F. since operation.

October 7th.—Temperature 101.2° F. Examination of wound shows a pustule on right side of bladder. This was laid open; drainage-tube inserted. Urine very cloudy, and incrustations forming on edges of wound. Has cough. Oil of gaultheria, gtt. v., t.i.d., and lithiated potash given. In this case a fistula persisted, which was scraped out and finally closed, and patient discharged cured.

CASE VI. *Supra-pubic Cystotomy for Removal of Foreign Body.*—July 25, 1888. G. A. V——, aged forty-one, United States. Ten years ago received fracture of last dorsal and first lumbar vertebræ, and since that time has had to use catheter to draw off his urine. A week ago, while introducing a metal spiral catheter, broke off a piece two inches long, which remained in the bladder. At my office I removed a piece of this with a lithotrite, but fearing laceration of urethra in any further attempt, advised cystotomy.

August 3d.—Operation. Ether. Catheter readily removed. T-drainage-tube.

August 8th.—No elevation of temperature. Tube removed.

August 17th.—Wound closed.

August 25th.—Discharged cured.

CASE VII. *Supra-pubic Cystotomy for Chronic Cystitis.*—N. U——, male, aged forty, laborer. Came under observation in 1888. He gave a history of chronic cystitis, lasting for more than one year. The urine did not contain pus or epithelia in sufficient quantity to indicate severe inflammation of this organ, and the patient was ordered full diet, alkaline drinks, and tonics. After eight weeks, no benefit having been obtained, it was determined to explore the bladder, and the high operation was done in December, 1888. No tumor was present, and the lining membrane of the bladder was only slightly injected. A drainage-tube was left in for three weeks, then removed, and the wound closed promptly. The patient's condition improved rapidly, and he was discharged certainly relieved and probably cured.

CASE VIII. *Supra-pubic Cystotomy for Vesical Fistula—Recovery—Cure.*—I. G——, aged sixty-eight, male. Was first seen September 2, 1888. He had been operated upon in May, 1888, by the high method, and a large stone removed. A fistula persisted, and on September 24th I cut into the bladder through the old cicatrix, dissected out the indurated tissues, enlarged the opening in the bladder by free incision, inserted a drainage-tube, which was removed on ninth day. On twenty-sixth day the wound was closed, and on November 7th patient discharged cured.

*The Operation.*—The preparation of the patient should be as for any ordinary laparotomy, for it is always best to have the bowels cleared out. The pubes should be shaved and a thorough disinfection made. After the anæsthesia is established the sacrum should be placed on a block or cushion high enough to give a decided tilt to the trunk, thus causing the abdominal viscera to gravitate toward the diaphragm. The bladder should now be washed out by injecting and evacuating through a soft catheter about twelve ounces of warm boracic acid solution (gr. v.–x. to ℥ j.). This should be repeated several times, especially when there has been a chronic cystitis. For lifting the bladder, a Barnes dilator or rectal bag well lubricated is introduced into the rectum and filled with from eight to ten ounces of water. About twelve ounces of warm boracic acid solution is thrown into the bladder. To prevent escape of this fluid, a string may be tied around the penis or a plug placed in the female meatus.

A longitudinal incision is made, about three inches long, directly over the symphysis pubis. The muscles being separated, the operator comes down to the fat and loose connective tissue which occupies the space between the muscles and pubic bones and the bladder. In order to expose more freely this space, with the dull scissors the attachments of the muscles should be clipped for about half an inch on either side and blunt retractors inserted. Carrying the finger down closely in contact with the inner surface of the pubic bones, the anterior wall of the distended bladder may be felt, and with the nail or handle of the scalpel the areolar tissue may be lifted from the wall of the organ. Should the peritoneum dip down unusually low, it will also be carried up out of the way by this dry dissection.

The bladder-wall is now in plain view. Should any vessels be seen crossing the proposed line of incision, they should be secured by passing a needle armed with fine double catgut beneath them, tying and dividing between the ligatures.

On either side of the proposed incision a middle-sized silk thread should be carried into the wall of the bladder, to support this organ after it is emptied. It will not matter if the needle perforates the wall. The thread should be left as loops to be removed after the operation. The incision through the anterior wall is made in the median line by pushing a sharp knife through and cutting upward from one-half to one inch. The fluid contents immediately escape. The incision should always be large enough to admit the finger, and may be enlarged by dilatation or incision if necessary. All downward pressure on the anterior wall of the bladder should be resisted by tension of the silk loops, in order to prevent a separation of the bladder from the tissues in front of it. Foreign bodies, calculi, etc., may be removed with the finger or delicate forceps. When a neoplasm is to be removed, a larger incision may be needed, and the size of the tumor

will in part determine the shape of the incision. When it becomes necessary to inspect the cavity of this organ, or to apply the cautery, the wound may be enlarged by a transverse incision just at the upper margin of the pubic crest. When the large size of the neoplasm can be made out beforehand, the transverse incision alone may be required. This incision should extend through all of the tissues, separating the attachments of the muscles, but division of the internal pillar of the inguinal canal and ring should be avoided. I have not yet been compelled to use this method, but it has been frequently done and no serious inconvenience from division of the muscles has, to my knowledge, resulted. In removing tumors the sharp spoon has so far been satisfactory in my work. The attached portion should be scraped out, going well into the wall of the bladder.

Papilloma and epithelioma are easily removed, but tumors resulting from prostatic hypertrophy offer considerable resistance. The scooped forceps used in tearing away post-nasal polypi are well adapted to this operation. When the neoplasm is malignant in character the cautery should be applied to the attachment. The bladder should now be irrigated and clots and débris thoroughly removed. The question of immediate closure of the bladder by suture, or of drainage by the T-tube, and subsequent closure by granulation, must depend upon several conditions.

Drainage is indicated: 1, When there has been severe and long-continued cystitis; 2, when intra-vesical hemorrhage is considerable; 3, when, from any cause, as thickness of the abdominl walls and consequent depth of the wound, disease of the walls of this organ, failing condition of the patient, etc., further operation may not be called for.

Should closure be determined upon, proceed as follows: Draw aside the edges of the wound down to the bladder with wire retractors. By traction on the silk loops already fastened into the bladder bring this organ as high up as possible. With a fine curved needle, armed with a small-sized catgut, insert the interrupted suture after the manner of Lembert's intestinal suture. The needle should not be made to penetrate the mucous membrane but be passed about one-eighth of an inch through the muscular substance, emerging just on the edge of the wound, then carried across to the opposite side and into the bladder-wall in the same manner. The stitches should be about one-eighth of an inch apart. By this suture the outer surface of the bladder is turned in and held in apposition. The superficial wound may be partly closed at the angles, but over the line of sutures in the bladder iodoform and sublimate-gauze packing should be used, and this part of the incision treated by the open method; for should the bladder leak the patient would be safe. A soft catheter should be placed through the urethra to keep the urine constantly flowing away, or it should be drawn off at frequent intervals. An accumulation of urine would endanger the line of sutures. The catheter should be discontinued about the tenth or twelfth day.

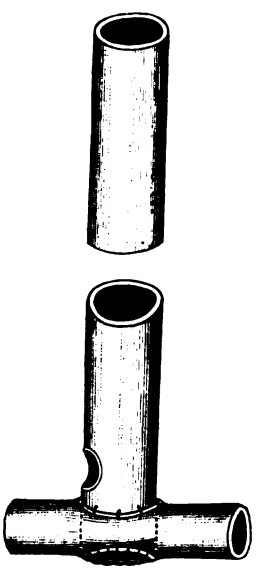

FIG. 1. — Treudelenberg's T-Drainage-Tube.

For drainage the T-tube is employed. This should be of soft rubber and about one-fourth of an inch in its lumen. It is carried into the bladder so that the cross-piece is well into the cavity and the wound packed snugly with iodoform gauze. After the patient is put to bed the lateral position should be maintained. A long tube should now be connected with the T-tube, and this fastened so that it will make traction on the bladder. This longer tube leads over the side of the bed to a vessel into which the urine trickles continuously. Every two or three hours during the first forty-eight hours the long tube should be disconnected and the bladder irrigated through the T-tube by injecting four to six ounces of warm boracic-acid solution. The irrigations may be less frequent after this and the tube removed from the fourth to the tenth day. The earlier the tube is removed after the fourth day the better, for as soon as adhesions have formed around the edges of the wound the danger of infiltration is avoided.

Supra-pubic cystotomy has at various times in the history of surgery been brought prominently before the profession, only to achieve a short-lived popularity and then to be practically abandoned. It is safe to say that within the last five years it has attained a prominence never before secured, and I think it is equally safe to assert that from its present established position it will scarcely again recede.

The greater perfection of surgical practice in our day, the proper selection of cases, the preparation of the patient, etc., have combined to lower the death-rate after a procedure once considered formidable.

*Conclusions.*—1. For the removal of tumors there can be no hesitation in preferring the high operation to perineal cystotomy. By no other method can a safe and thorough removal of a neoplasm be effected. 2. In vesical calculus, without regard to size, the supra-pubic operation is preferable in hypertrophy of the prostate, where this organ is elongated and thickened, and has thus made the cavity of the bladder more difficult of access. 3. In large calculus —two inches in diameter and over—the high operation should be chosen. 4. For stone in the female bladder it should be invariably selected, when the calculus is too large or too firm to be crushed and removed per urethram. 5. In male children perineal section for stone may be preferred, since the perineum is not deep, the organ quite easy of access, and the after-treatment less troublesome. 6. In female children supra-pubic cystotomy should be done when the calculus is more than one-half inch in diameter. 7. For foreign bodies other than calculi, not safely removable with the lithotrite, the same rules would apply as for stone. 8. As between lithotrity and cystotomy I am of the opinion that when the urethra is normal, the bladder not materially diseased (and therefore not in great need of the rest which drainage after cystotomy secures), the stone soft enough to be crushed, and not over two inches in diameter, lithotrity should be done, *always provided that the operator is well versed in the technique of this operation.* I do not know of a procedure requiring greater skill, a more practised hand, and clearer head than lithotrity. Given a tyro at both procedures, then by all means the high operation, for here, if the lines are adhered to, the end will be attained. 9. In drainage of the bladder for chronic cystitis in women, when the drainage is to be continued for many weeks and a urinal worn, the vaginal operation is indicated. For temporary drainage the high operation is best, since the wound closes spontaneously after the tube is removed. 10. In males I prefer the high section for drainage, for the reason that a fistula in the perineum offers more difficulty to close than one through the abdominal wall above the pubes. 11. I consider the chief objection to this operation to be the tendency to establishment of a fistula in the track of the wound. It is probable that this tendency will be greatly lessened by an early removal of the tube, say on the third or fourth day.

CASE. *Deligation of the Left Common Carotid and Left Subclavian Arteries, for Aneurism of the Aorta—Death.*—O. P——, aged forty-eight; United States; builder by occupation. Came under observation through the courtesy of Professor R. C. M. Page, February 16, 1889. History of syphilis commencing seventeen years before. Had been treated only a few months after chancre appeared. For a number of years patient had cough, with occasional attacks of dyspnœa. Sixteen months ago these symptoms increased, and, accompanying them, has severe pains

referred to the anterior part of the chest about the heart. Appetite good; bowels regular.

February 20th.—Temperature, 101°; respiration, 28; pulse, 132; systolic murmur loudest at right second interspace and travelling along arch of aorta; no expansion of innominate or carotid arteries. Radial pulse at left wrist weaker than right. Urine, 1.026; albumen, and numerous hyaline and granular casts. Patient deeply cyanotic. Moist râles over both lungs, loudest over right.

February 21st.—Oxygen gas, five minutes every half-hour. Temperature reached 104° F.; antifebrin. Diagnosis: Aneurism of transverse aorta; compression of trachea; chronic pneumonia. Operation advised as last resort.

February 22d.—I tied the left common carotid and left subclavian third division with large catgut; chloroform. The operation, including the anæsthesia, lasted thirty minutes; both incisions closed with catgut sutures. Patient rallied well considering his bad condition.

February 23d, 6 P.M.—Temperature, 103.5° F.; breathes laboriously, but evidently easier than before operation; pulse on right side full, absent on left.

February 24th.—Temperature, 101.4° F.; respiration, 28; pulse, 120; symptoms of uræmic coma appeared; only five ounces of urine from 5 A.M. to 11 A.M.; poultices over kidney region; hot-air bath.

February 25th.—Died from renal and pulmonary asphyxia at 3 P.M., seventy-two hours after operation.

*Autopsy.*—Right lung solidified in great part; large syphilitic gummata scattered throughout—fibrinous pleurisy; left lung about normal. Heart: Hypertrophy and

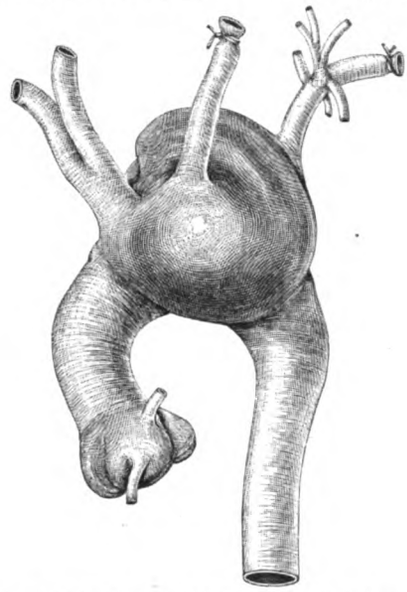

FIG. 2.—Showing Aneurism of Transverse Arch of Aorta.

dilatation of left ventricle; aortic valves roughened; arch of aorta dilated. Commencing with the origin of the left carotid, and extending beyond that of the left subclavian artery, an aneurism was situated. It was spherical in shape, about three inches in diameter, filled entirely with firm, stratified clots, and pressed heavily on the trachea and œsophagus from the seventh cervical to the second dorsal vertebræ. The chief direction of the tumor was upward and backward. Kidneys small, cirrhotic, coarsely granular surfaces, and adherent capsules. The aneurism was evidently due to syphilitic arteritis. Dr. Page had employed iodide of potassium faithfully for several weeks before I saw the patient, and although the consolidation of the aneurism was well advanced, the symptoms of dyspnœa increased. The increasing dyspnœa was in all probability due to the progressive consolidation of the right lung, an acute localized pneumonitis spreading from the gummatous patches.

The iodide of potassium did not favorably affect this process. I based my hopes of benefit from the operation upon the consolidation of the aneurism as a result of the deligation of the two arteries coming off in connection with the sac, thus damming the blood back upon the aneurism, changing the direction of the current, with more or less arrest of the circulation and consequent coagulation.

That the distal ligature will effect the gradual formation of an organized clot in an aneurism not immediately connected with the vessel tied, is now accepted.

In the *American Journal of the Medical Sciences* for January, 1881, I published a case in which, for a large aneurism of the ascending aorta, I tied the right carotid and subclavian arteries with immediate and marked beneficial effect. The tumor had eroded one rib, and presented as a large swelling, with a wall so thin that rupture seemed imminent, and through which the rush of blood and aneurismal tremor were easily felt. The tumor diminished rapidly in size, and the patient was greatly improved. She died of acute diarrhœa one year after the operation. The autopsy showed an aneurism springing from the ascending aorta, about three inches in diameter, filled with organized clot in its lateral and posterior portions. On the upper anterior surface, which had cut through the rib and sternum, the sac was thin, with a recent clot filling a space not quite one inch in diameter. The tumor was practically solidified, and had this patient not returned to her dissipated habits (alcoholism) I do not doubt her recovery would have been complete.

CASE I. *Deligation of both External Carotid Arteries for Arrest of Hemorrhage from Tumor of the Naso-pharynx.—Recovery.*—W. M——, aged sixteen; April 17, 1889. In March, 1888, a tumor was removed, by means of the Jarvis snare, from the vault of the pharynx. It recurred, and was again in part removed by the galvano-cautery loop on April 20, 1889.

During the night of April 27th, a severe hemorrhage occurred from the tumor, and on the morning of the 28th I tied both external carotid arteries between the lingual and thyroid branches. This operation was done preliminary to an attempt at removal of the neoplasm, but as the patient's condition was so bad the latter procedure was postponed.

On May 8th I split the soft palate, and with a key-hole saw I removed a part of the horizontal processes of both palate bones and the posterior portion of the vomer, to which bones the tumor was attached. This opening gave a full view of the vault of the pharynx and the neoplasm. With a Volkmann spoon I rapidly scraped away the attachment of the tumor from the vault of the pharynx. Notwithstanding the ligatures to the arteries, the hemorrhage was so alarming that I had to desist and rapidly plug the cavity with sponges. The patient is now under treatment by his father, a physician in Texas, who is applying at intervals the galvano-cautery to the region where the neoplasm was attached.

It has long been a matter of discussion among surgeons whether ligature of both external carotids should be done preliminary to removal of vascular tumors of the naso-pharynx.

In this case the benefit was very slight, as far as prevention of bleeding was concerned, when I removed the tumor ten days later; for by this time the collateral circulation had been established to such an extent that I was forced to desist, and to arrest the bleeding by packing with sponges.

It is of interest to note how thoroughly tumors of the vault can be seen by splitting the soft palate in the median line, and retracting the sides of this divided curtain. It is my opinion that this method will prove of great value when a preliminary tracheotomy is performed, and the larynx protected by packing the lower pharynx with sponges. Under such conditions the additional ligature of both external carotids should depend upon the vascularity and size of the neoplasm to be removed. This operation certainly renders the parts anæmic for several hours after the vessels are tied. It is not of value after

several days have elapsed, when the collateral circulation is re-established.

CASE II. *Ligature of the Right External Carotid, in removing an Epithelioma of Tongue.*—This vessel was tied preliminary to the extirpation of a number of infiltrated glands of the submaxillary and upper carotid region on the right side, and to removal of the right anterior portion of the tongue and the floor of the mouth. The patient recovered promptly without accident. The safety and propriety of this operation is now, I believe, universally accepted in surgery. I have tied this vessel about twelve times, successfully in each case, while the list is swelled now by many hundreds. Up to 1878, when I published my American Medical Association Essay on the "Carotid Arteries," in the whole history of surgery this vessel had been tied less than one hundred times, and not a single standard work on surgery of that day advised this operation in preference to deligation of the primitive carotid.

And yet forty-one per cent. died after this last operation, and only four and a half per cent. after ligature of the external carotid.

AMPUTATIONS.—Of the amputations which have come under my care, only three possess especial interest.

CASE I.—L. J. L——, aged forty-three, of Seattle, Wash. Terr., came under my care in December, 1888, with this history: While serving in Company B, Fifth New York Cavalry, at the battle of the Wilderness, May 5, 1864, he received a minié-ball wound through the left thigh, causing a comminuted fracture of the femur, about seven inches above the knee. He was taken to a field-hospital, cold-water dressing applied, and three days later

FIG. 3.—Bone showing effort at Repair after Gunshot Fracture of Femur. At *a*, sequestrum with two pieces of lead buried in the bone.

hauled in an ambulance about twenty miles to Fredericksburg, where a starch bandage was adjusted. This was removed later, extension made, union secured, and discharged as cured, September, 1864. In 1869 inflammation took place at the seat of injury, pus discharged, and several pieces of bone came away.

The sinuses persisted from this on to 1887, when a severe inflammation was established, and patient was compelled to use crutches. The discharge of pus increased, his health failed, and when I saw him, through the courtesy of Dr. Leo, of New York, in December, 1888, he was pale, emaciated, and evidently suffering from prolonged sepsis. There were six or eight sinuses opening out between the knee and trochanter, and the soft tissues were infiltrated with pus. A piece of lead had escaped through one of the openings a few days before. The urine was normal.

In consultation with Drs. Leo and Bryant, it was determined to explore the seat of injury and perform necrotomy or amputation, as the conditions might justify. I did this January 8, 1889. The soft parts were wholly undermined with sinuses running in all directions. The bone was, for about seven inches in its length, incrusted with a rough callus, with several large spines projecting. Six inches above the joint a large sinus led into the bone, and this was partially filled with a piece of dead bone. This was evidently the point where the missile had entered, for two bits of lead were buried in the bone at this point. Considering the bad condition of the bone, the extensive infiltration of the thigh, and the patient's exhausted condition, I determined to remove the member, and amputated above the middle of the femur. The patient made a good and rapid recovery, and returned to his home.

The interesting feature of this case is the length of time the pieces of lead remained in the bone before producing ostitis.

CASE II.—M. B.——, aged sixty-nine, residing in Western New York; was seen in January, 1887. He had been a healthy man up to three years ago, when he had diabetes mellitus. The sugar would disappear at intervals and then recur. In August, 1888, gangrene of the left foot was noticed, commencing in the great toe and gradually involving the foot. When I saw him the line of demarcation was not well established; the entire foot was swollen and œdematous, and the patient was evidently failing. He had been in bed four months, and was helpless. I amputated at the middle of the leg, using ether as the anæsthetic. The arteries were calcareous, and in order to hold them with the catgut ligatures I was compelled to include some of the soft tissues with the vessels. Without this the ligatures would cut through. The patient rallied from the ether, had suppression of urine, and died from uræmia thirty-six hours after operation.

This case was no exception to the rule that any operative interference is dangerous in senile gangrene with diabetic urine. And yet we know that the risk of amputation is justifiable when death from sepsis is inevitable.

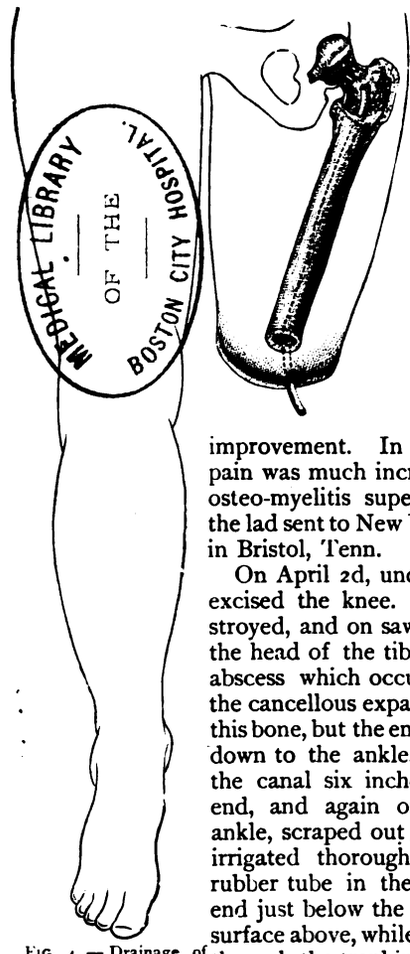
CASE III.—G. S. A——; aged twenty-four; United States; single; stenographer. He had been operated upon in Roosevelt Hospital for osteo-arthritis of the left knee, for which exsection of the joint was done.

Osteo-myelitis of the tibia and femur was discovered when I saw the patient, several weeks later, and for this I amputated the thigh, just above the knee, on February 4, 1889. On cutting through the bone I found the medulla entirely destroyed, the canal containing a purulent fluid which discharged itself as the femur was divided. The shell of compact tissue was very thin, leaving the medullary cavity about twice the usual size. As the patient's condition was too feeble to withstand the risk of a prolonged operation, as well as the increased danger of amputating nearer the hip, I rapidly scraped out the canal up to the trochanter, irrigated it with 1 to 1,000 sublimate solution, and introduced a drainage-tube long enough to extend from the trochanter out through the flaps. This tube was not perforated, so that when the nozzle of the irrigator was introduced the stream of sublimate solution passed entirely up through the tube and flowed out by way of the medullary canal.

The tube was shortened one inch a week for five weeks, and was entirely removed at the end of eight weeks. The patient recovered without any distress, and is entirely well, with a long, healthy stump. This is one more case in proof of the great reparative power of bone, if only healthy drainage is secured.

Of the excisions, the following four cases are here reported.

Excision of Knee-joint.—Case I.—W. A. R— , aged nineteen; United States; student; first seen in June, 1888. Two years before this date he began to have pains in the left knee, not severe in character, but enough to annoy and constantly irritate and alarm him. Under the advice of his physician he began the use of crutches, and later a plaster-of-Paris dressing was applied at intervals. The knee continued to enlarge, though it was not painful unless he put his foot to the ground and brought the weight of the body upon it. When seen by me, in June, 1888, he was in about the condition just described, and hoping to save him from an operation, and with the advice of Dr. V. P. Gibney, a Thomas long splint was applied. This was faithfully worn, but without improvement. In February, 1889, the pain was much increased, symptoms of osteo-myelitis supervened, and I had the lad sent to New York from his home in Bristol, Tenn.



MEDICAL LIBRARY
OF THE
BOSTON CITY HOSPITAL

Fig. 4. — Drainage of Cannulated Femur in Amputation for Osteo myelitis.

On April 2d, under ether narcosis, I excised the knee. The joint was destroyed, and on sawing a section from the head of the tibia I opened into an abscess which occupied not only all of the cancellous expansion of the head of this bone, but the entire medullary canal down to the ankle. I trephined into the canal six inches from the upper end, and again one inch above the ankle, scraped out all diseased tissue, irrigated thoroughly, and inserted a rubber tube in the canal, leaving one end just below the level of the sawed surface above, while the other projected through the trephine hole at the ankle. The condyles of the femur were sawn away, the bones fastened together with my steel fixation drills, and the wound closed.

April 3d.—Doing well, slight oozing; temperature, 100.6–102.2° F. Given antipyretics and stimulants.

April 4th.—Temperature, 100.8–101° F. Received antifebrin, gr. v., once, at 4.15 P.M.

April 5th.—Temperature, 99.2–101.8° F. Doing well. One dose antifebrin, gr. v., at 6 P.M.

April 7th.—Temperature since April 5th, 99.2–100.4° F. No antipyretics.

April 14th.—To-day temperature 98.6° F., all day, for first time. Quinine stopped.

April 17th.—Doing well.

April 27th.—Dressed. Union perfect along line of section; all drains and drills removed from about knee-joint. Perfect asepsis. Long drain extending down shaft of tibia pulled out and shortened. No irritation of skin about joint. Light gauze dressing applied.

May 4th.—Plaster splint put on, extending from hip to ankle. Patient to be up.

May 17th.—Long tube removed from tibia. Patient's condition improving.

May 20th.—Plaster removed; obliged to insert small drain in tibia shaft. A light dressing applied, with poplar splints. Patient up and about. Improving rapidly.

Case I.—F. B——, aged twenty-four, Italy, laborer, seen first January 31, 1889. Three years ago began to have pain in right knee, which was soon followed by swelling. For two years had used cane or crutches. Of late has had fever daily. Present condition: Knee swollen, synovial pouches very prominent, leg flexed on thigh about forty-five degrees; temperature, normal; general condition, fair.

February 5th.—Operation; ether.

February 16th.—Complains of slight pain in knee; temperature ranged from 99° to 101° F. since operation; urine has to be drawn off occasionally by catheter.

February 21st.—Wound dressed first time and drills removed; healing nicely.

February 28th.—Dressing changed.

March 6th.—Dressing changed.

March 13th.—Dressing changed; about on crutches.

April 3d.—Discharged perfectly cured.

Case II.—Amanda R——, aged twenty-six; United States; cook; first seen March 21, 1889. Family history negative. Patient has had slight cough for five or six years; once had hæmoptysis. Ten months ago developed sudden painful swelling of left knee; integument reddened. This lasted for three months, during which time there was continuous fever. Leg became flexed on thigh, and was never since extended. Present condition, fair; temperature, 98.6° F.; left knee, irregularly enlarged; leg flexed at ninety degrees on thigh; almost complete anchylosis; attempts at motion painful.

*Diagnosis.*—Subluxation and partial anchylosis from rheumatoid arthritis.

March 26th.—Operation; ether.

March 27th.—Rested well; temperature, 99.6° to 100.6° F.

April 6th.—Temperature, 98.6° to 100.4° F.

April 22d.—Wound dressed first time; union perfect; drills removed.

May 2d.—Wound again dressed.

May 16th.—Discharged perfectly cured.

Case III.—Mrs. T. O'R——, aged thirty-three; housewife; Ireland; seen first, December 26th, with history of painful enlargement of left knee for more than one year. She could not walk without crutches, and was evidently suffering from chronic sepsis.

December 27th.—Excision of joint under ether narcosis. Wound cleansed and surface freely dusted with iodoform.

December 30th.—Temperature, 102° F., controlled by antifebrin, but would rise when effect of medicine wore off. As sepsis was scarcely possible, iodoform poisoning was suspected, and, on examination of the urine iodine was found present.

January 4th.—Wound dressed.

January 13th.—Wound dressed.

January 21st.—Wound dressed; drills removed.

March.—Patient moving about on crutches. Small sinus on right anterior aspect of knee. In April this was laid open, scraped, and healed quickly. Patient cured.

*Résumé.*—These cases, with others heretofore operated upon, confirm the freedom from danger which this procedure enjoys. I have so far not lost a single case of excision of the knee. Occasionally failure of the operation occurs as a result of recurrence of ostitis in the bones at or near the line of coaptation. The chief interest is in the complete fixation, by means of the drills, which gives perfect rest. This, with the aseptic technique and dressings, permits the parts to remain undisturbed until union is secured.

In three of these cases the original dressing was changed on the twenty-fourth, sixteenth, and twenty-seventh days, respectively. In the other instance too much iodoform necessitated a change on the eighth day. In cases of extensive disease of the tibia or femur, where the patient is greatly run down, amputation should be seriously considered in place of exsection. Yet the safety of exsection would justify an effort of saving the limb where doubt may exist.

The operation which I prefer is as follows:

Under the strictest asepsis the leg is cleansed, the foot

elevated to empty the extremity of blood, and a rubber tube tourniquet applied above the middle of the thigh.

With the leg straightened out, an incision is made across the centre of the patella, and down on each side, until the level of the posterior surface of the tibia is reached. These points must be low in order to secure free drainage. The skin flaps or cuffs are now dissected and rolled up until the upper one is turned back from two to three inches, the lower about one and a half inch. As the flaps are held well away by assistants, the operator cuts down to the femur through the tissues, parallel with the attached edge of the reflected flap, lifting everything from the anterior aspect of the femur and its condyles, together with the patella, the attached fringes, ligamentum patellæ, and coronary ligaments, thus clearing in one mass all the tissues which envelop the anterior three-fourths of the joint.

By sharply bending the knee the crucial ligaments are exposed and divided, the lateral ligaments cut away, and the disarticulation effected. In stripping the attachments of the ligamentum posticum Winslowii from the tibia and femur, the operator should closely hug the bone and thus avoid wounding the vessels. This dissection should extend about three-fourths of an inch below the level of the tibia and one and a half inch above the lowest surface of the condyles. Determining now the amount of bone necessary to be removed, a cloth retractor is applied so as to protect the soft parts from bone detritus or injury, and a slice thick enough to freshen the head of the tibia is sawed away, as nearly as possible parallel with the normal plane of the articular surfaces. Should the section expose a focus of disease which dips down into the bone, this should be cleared out with a scoop or Volkmann spoon, and finally mopped with a strong bichloride solution (1 to 500).

The section through the end of the femur should now be made. It follows that if the limb is to be straight in the position of anchylosis the sawed surfaces of the two bones must be parallel. I have found it of great value to employ this method. By pulling on the foot the limb is fully straightened, and the articular surface of the femur separated from the sawed surface of the tibia. If the operator will now start the saw into the femur, sighting by the flat face of the tibia, the instrument will cut directly parallel with this. If by error the section of the tibia has been slightly oblique, that of the femur will have a like obliquity, and therefore the bones will fit snugly with the extremity straight.

The next step is to dissect away with forceps and curved blunt scissors all the diseased capsule. This should be done thoroughly, and even the bursæ that communicate with the joint should be cleaned out. If care is not taken, a portion of the sac which extends up beneath the quadriceps tendon will not be removed. All bleeding points should be tied with catgut and all hemorrhage stopped. The bones are now brought in exact apposition, and while so held the steel drills are introduced. I usually carry two of these in from below upward, passing them through the skin about two inches below the sawn surface of the tibia, and directing them obliquely through the tibia into the femur. When the end of the drill has reached the compact substance of the femur, it is stopped, the handle unshipped, and the drill left in position. Three are used, one on either side from below, and one directly down the median line from above, entering the femur and passing into the tibia (Fig. 3).

As the leg is now held steady, the edges of the wound in the skin are sewed together with catgut, and two short bone-drains inserted at the inferior angle. I no longer use rubber drains, having had considerable trouble with the sinuses that persist after their removal. If the absorbable bone-drain is not at hand, twists of catgut will suffice. Aseptic dressings and layers of veneering as a splint are applied under firm compression of a roller. Over all one layer of starched crinoline bandage is placed. This dressing is allowed to remain on for from two to three weeks, and when changed the drills are pulled out.

## SHAKEN MILK.

By JOHN C. MORGAN, M.D.,
PHILADELPHIA, PA.

EVERYWHERE this dietetic paradox confronts the physician, viz., that milk—cows' milk—is the best possible representative food; that it "contains every element of nutrition," hence, that it is *the* typical diet for the sick of all ages, as well as for the healthy; this on the one hand, and on the other, that there are few articles from which worse results may accrue to individuals, young and old.

"Starving on cows' milk" is a common phrase; and "milk is bilious," or "constipating," or causes diarrhœa, or headache, indigestion, etc.; and these often parry our thrusts at malnutrition. "Acidity of cows' milk," the massiveness of its curd contrasted with human milk, with its fine flaky curd, evidencing faulty digestive processes; its deficiency in oil and sugar—all these are quoted, endlessly, to explain the paradox, and doubtless all are significant; but there are other important considerations which are less considered, and these are, in my judgment, largely as follows:

Firstly, human milk, drawn by the child, is a nascent life-product. Cows' milk, at its first emission, is equally so. Secondly, both are living fluids, and their contained cells are the site of vital metabolisms, all, doubtless, promotive of assimilation and of digestion itself. Thirdly, their oil globules and casein granules are sundered and enveloped by their containing shells of albumen and the watery menstruum.

Milk which has died, whether human or cows' milk, has ceased to be nascent, has ceased its living metabolic cell-mutations, has become a mere physical or mechanical admixture of bodies of unequal density and specific gravity, whose particles separately mass themselves, and within a few hours, if undisturbed, form crude strata, as cream, heavy caseous milk, and whey; each, after longer intervals, becoming very distinct, as is proved by the so-called "candles" formed in the large test-tubes in use in condensed milk factories. Preservation on ice does but promote this change. Sterilizing processes, *per contra*, interfere with it, over and above the intended germ-destruction, inasmuch as the high heat, with agitation, prevents rapid separation. The housewife recognizes the same principles when preparing "curds and whey," or "slip," with milk and the pepsine-bearing rennet, choosing a cold and quiet place for the setting of her pan, her object being to obtain a half-digested, massive, unruptured curd, with its transparent substratum of watery albumino-saline fluid, or whey. Most stomachs can easily complete the digestive process thus begun—for it is nothing else—and it rarely disagrees with anyone. Should it do so, we may, by beating, or shaking it, break up the curdy mass (with the aid of an admixture of atmospheric air), thus reducing it to the finely comminuted flaky state so admired in "mothers' milk," and intimately mingling it with the whey at our option. Afterward, the process of curdling being complete, these particles have but feeble tendency to reunite; are, indeed, until decay sets in, in excellent condition for the full play of the digestive organs.

Cows' milk, as received from the milkman, especially in hot weather, has undergone an incipient change of like nature. Chilled and quiescent during the night, the evening's milk is combined with that of the early morning, but both are carefully deprived of all remaining "animal heat." The whole becomes as one by this treatment. The motion of carriage opposes, but the tendency to mechanical separation has already fairly set in. Received now at our dwellings, and transferred to the refrigerator, this separation goes on rapidly, and indigestibility progresses *pari passu*.

To counteract this change, so far as may be, would seem to be the dictate not only of science but as well of common-sense. To prevent the gastric struggle with curdy masses, one need but insure the comminution of those masses, and thus invoke mutually repellent forces of

the minute particles of oil, water, and casein. The rapid digestion of each and all of these in the gastric and pancreatic juices should now occur without the aid, ordinarily, of pepsin or pancreatin, artificially introduced.

Such is the theory I would propound, and I have witnessed a number of cases of its practical and successful application. One of these is a stout, florid gentleman, of about sixty years, who is subject to the usual disturbances from drinking even the best quality of milk. The preparation now so popular under the name of "milk-shake," at an extremely low temperature too, agrees with him perfectly, and is readily and speedily digested. Another case is that of a physician, fifty-two years of age, convalescent from malarial fever, for whom I prescribed a milk diet; but who met me with the fatiguing statement that it was always disastrous to him. Lime-water did not better the matter. I now advised that it be violently agitated by shaking or beating, with a view to comminution of its massive elements—the oil and the casein—and their thorough diffusion in the whole of the fluid portion; this preparation to be taken in small portions until the teacupful was finished. This was duly accomplished by means of a conical tin cup, such as is used by bar-tenders, being closely fitted over the top of a glass of milk, and the whole vigorously shaken for some time just before drinking (in sips, as directed). The result was really charming. His own report was: "Here is a man who never has dared, in many years, to drink a glass of milk, but who now takes it, in the new way, every day, and is building up on it."

The use of milk just drawn from the cow is also important for infants and weakly persons; but most people can do admirably well, I opine, on "shaken milk."

Judging from my own experience, I think it is not too much to predict that in the future the medical and other attendants in typhoid cases, perhaps in infantile disorders and in many others in which patients refuse everything in the way of "sick-diet," and crave everything which they must be denied—particularly as to those who "cannot take milk"—will find the solution of the perplexing but essential problem in providing, as an indispensable utensil, the bar-room tin, and regularly using it, in the preparation of shaken milk.

A dilution of milk with one-tenth of water "scalded," not boiled, and taken hot, or even ordinary hot milk, is a noble stimulant (*versus* alcohol) in threatened collapse, and in debility in general. If shaken, also, it must prove invaluable in a wide range of low cases.

When a cold drink is more suitable, as in some febrile conditions, cracked ice may be added to milk before shaking; and lastly, when the taste is fastidious, strawberry or other fruit-syrup, or any other approved ingredient may also be introduced.

---

THE INTERNAL USE OF CHLOROFORM.—Dr. Henry Shimer, of Mount Carroll, Ill., writes: "The letter of Dr. Wallace, in THE MEDICAL RECORD of July 20th, recalls a case that I had many years ago. I was called, in the early evening, to see a large, muscular man, who was in convulsions from alcohol. The spasms were tonic, the knees being drawn up to the chest and held there as rigid and immovable as the roots of an overturned stump. I learned that the man had had such attacks before, and that chloroform only gave him relief. I accordingly gave him six ounces by inhalation, with the effect of causing intervals of relaxation, but the spasms frequently returned. I sent the bottle to be refilled about midnight. I was then tired of watching with the patient, and began giving him chloroform internally in teaspoonful doses every fifteen or twenty minutes. After administering about six doses I was able to leave my patient. The only remark he made about it was after the first dose, 'There, you have played the devil with my mouth.' The next day he was able to go out, though not yet entirely recovered from his two weeks' spree."

## RÉSUMÉ ON MATERNAL IMPRESSIONS.

BY WILLIAM R. LOWMAN, M.D.,

LECTURER ON PHYSIOLOGY AND HYGIENE M. H. S.; SURGEON TO PRISON AND ALMSHOUSE, ETC.; MEMBER OF COUNTY BOARD OF EXAMINERS, ETC.; ORANGEBURG, S. C.

UNDER this heading may be classed all those peculiar freaks of nature connected with the genesis of species, all abnormalities resulting from nervous, psychic, and hæmatic influences that affect the fœtal subject while yet in the bosom of its mother, and all anomalies of spermatogenesis. But, specifically, in this let us consider the departures from "primogeniture" in woman and see how and why "this plastic ideal of the mother's emotional impress can be made to subserve for the congenital welfare of the child in utero," and see if sufficient demonstration can be found to show the mother's power for transmission of mental impressions as in those that impart likeness of physical configuration.

I. *History.*—Records are rich in stories showing the effects of maternal impressions. The ancients fully believed in them, as we have attested by Baptista Porta, Furnelius, and others. The belief that psychical, mental, and physical impress is implanted on the fœtus has always found a responsive chord in writers of all ages, not only from love of the mystic and wonderful that belonged to some, but also, we are forced to conclude after careful study, from actual and positive knowledge of such things by many of these authors. Of course, being of inferior knowledge, the majority therefore were easily led into erroneous conceptions often, but, with the light of succeeding ages focalized and knowledge concentrated and purified, we are compelled to give credence to the honest and oftentimes abstruse (comparatively) dissertations of Hippocrates and Fabius Quinctilius,[1] even though they assure, with seeming sincerity, that white parents begat African-hued offspring perforce of the antenatal impression of pictures of some Hannibalian hero hanging in the connubial chamber. Be this as it may, in sacred history[2] we have at least one well-attested case of the result of impression upon animals during heat in which Jacob craftily outwitted his father in-law.

Were we to search medical literature from remote antiquity, through all there would be a connected and unbroken chain of records from the markèd Cain and cursèd Ham on through mediæval folios, through Roman and Grecian history, mythical and true, to this day; and we would find numberless instances of strange freaks of nature and Minotaurean wonders attributed to sensorial and psychical impressions. The greater number are not reliable, but still there is sufficient to be of positive value. The tendency of the day is decidedly agnostic, and especially is this sceptical inclination manifested in regard to everything that is immaterial, that is not tangible. A man of science who meets a new fact simply arrests his judgment until he can explain it. The dogmatist takes refuge in the intellectual indolence of denial. Every scientist is naturally a materialist, but there are many who cannot see beyond the limit of their narrow sphere and who will not look beyond the tip of their Æsculapian proboscis, and anything that cannot be dissected, vivisected, or subjected to the microscope, kymograph, and balance is cast aside as valueless and without foundation. Such are hot-house plants developed in the labyrinths of laboratories, and, when subjected to the light of practical truth, it matters not how much sneering hauteur and enthusiasm they have for their pseudo-scientific knowledge, the well-attested results of observation must and will drive their puny theories to the wall. Often, also, crazed by a desire emanating from a would-be authorship, they proclaim theories completely at variance with facts for the sake of notoriety.

Many attempt to demonstrate the erroneous character

[1] According to Cœlius of Rhodes, cited in De Morbis Cutaneis. Dan'l Turner, London, 1716.

[2] Book of Genesis, chapter xxx.

of observation. I confess myself to have been very sceptical in regard to the effect of maternal impressions until facts compelled me to admit that a single well-observed and carefully tested fact is sufficient to upset a dozen *a priori* theories. Scepticism is the order of the day, and a sceptical incredulity is considered an evidence of superior wisdom. On anatomo-physiological principles the influence of maternal impressions in the production of monstrosities has been denied. The "coarse materialism" of many has ignored the demonstrated fact that other psychological impressions are admitted to produce other physical effects. Our mental impress is left on the offspring.

II. Can we assign any cause outside of an unsatisfying Kismet; or shall we, with the Moslem, exclaim: "Allah is good, Allah is great! What is to be will be—Kismet!" Or can we, by a close study of spermatogenesis, receive some light on this hitherto darkened subject? A good part of work that has been recorded is chiefly based on observations on lower animals, in whose analogous genesis may be reflected some light on the human phase of the problem. Our comprehension of the subject of heredity also affords a ray. It is known that an impression is much more easily received and transmitted to the offspring by an animal—this is to be accounted for by lack of the reasoning inhibition possessed by man. Heredity, well studied, affords a guide to a partial explanation. Criminals, according to latest researches, are born in a nascent state, to be developed by opportunity, and if this be so the converse must be true. The law of heredity shows that the mother, in most instances, stamps her individuality on the offspring more frequently than does the father; therefore an impression made on her, transmitted by nervous force direct or through control of hæmatic supply of the blastema, must be capable of a moulding influence. Is this strange? Lockwood [1] tells us that a human embryo twenty-three days old is not larger than a common house-fly ($\frac{1}{32}$ of an inch). Would it not be an easy, yea, plausible thing that, an impression could affect this minute object still in an unmoulded, unformed, and plastic state? We know that monstrosities are most frequently met with among impressionable people; that emotional disturbance of the mother can and does affect the child in utero. We know that the milk of an angry mother is liable to sicken a child, and must not the utero-fœtal connection be much more intimate? The embryo, prior to the beginning of the third month, is much more easily affected than later. This is consistent with embryological law. In embryological experimentation in production of monstrosities by artificial methods, "an interference with development at an early period produces a far greater malformation than one at a later period." [2] A philosophical explanation of the results of these maternal impressions would regard them as arrest of development, showing itself in atrophy or hypertrophy of a given part.[3] The impression may be sensorial or psychical, and may be of either a sudden and vivid, or of a continuous nature. But how do these impressions affect the child in utero? Is it through nerve-force regulating the flow of blood? Would this be an explanation to this seemingly inexplicable question? It is not so singular as it first seems that the transmission of a transient impression need not necessarily affect the mother to a great extent, yet materially injure the plastic, unformed embryo. There is no direct nervous connection, so far as we know. Is there something pertaining to this solution buried in nature's mystic breast; is there some channel yet to be discovered through which these influences find transmissal? The experiments of Dareste, Symkiewicz, and Fol in varnishing eggs in different ways, irregularly heating them, subjecting them to the motion of a railway car, produced different monstrosities; yet, while many scientists, great minds, and embryologists like Thomson, Geoffroy St. Hilaire, and Carpenter, and physicians like Velpeau and Flint were firm believers in it, a tangible cause has not yet been found. But, even though an almost inexplicable phenomenon, the effect of maternal impressions cannot be gainsaid by opponents. And if such a thing is or has been attempted, to him who does we would ask an explanation of a few acknowledged facts, to wit: vital force, genesis, evolution, and heredity.

Dr. Archibald Dixon [1] draws the following inferences and facts in reference to cause and effect after impression:

*a.* That during embryonic existence certain parts may be hindered or arrested in their development, while the other organs not directly connected with them may continue their evolution and become fully developed.

*b.* That ectopia viscera of the abdomen, spina bifida, cleft palate, hare-lip, webbed fingers and toes, etc., are only evidence of arrested development of embryonic abdominal, spinal, and maxillary processes, or, in the case of webbed extremities, the continuation of the embryonic hand or foot of the second month.

*c.* That any agency causing arrest of development of any portion of the fœtus must necessarily operate prior to the evolution of the part.

*d.* That the cause of the arrested development may be local or general, as injuries to the mother's abdomen, diseases of the uterus or its membranes, hereditary transmission of deformity. (We add positively sensorial and psychic impressions made on the mother!)

*e.* That excessive development of parts of the fœtus may obtain, resulting in nævi, aneurisms by anastomosis, supernumerary fingers and toes, etc.

*f.* That intra-uterine amputations are the result of amniotic bands or placental adhesions, fracture, or from constriction of a loop of the umbilical cord.

*g.* That amniotic bands or placental adhesions result from inflammation of the uterus, decidua, or inflammatory disease of the fœtus. (How caused?)

*h.* That false membranes causing these amputations may be afterward absorbed, as also the amputated extremity.

*i.* That so-called double monsters are the result of the development of double cicatricula on the blastodermic membrane of a single ovum.

*j.* That twins with a common chorion also result from the development of a double cicatricula on the blastodermic membrane of a single ovum.

*k.* That in either case there is always unity of sex.

*l.* That the nearness of the primitive traces to each other determines whether the impregnation will result in separate twins, or a double monster.

*m.* That in twins with a single chorion, or anastomosis of placental vessels, one fœtus may become perfectly formed while the other becomes monstrous.

*n.* That the development of the abnormality in such cases depends on local anatomical causes and is governed by fixed laws. (What are they?)

*o.* That every known malformation in the human race has its analogue in the lower animals, birds, fishes, and reptiles.

*p.* That arrest of development at any of the stages of embryonic life results, in part or in whole, in a permanent embryo of the stage at which the arrest took place.

III. Dr. Spitzka [2] classifies maternal impressions and their ensuing deformed results thus: "First, those in which there is no resemblance between the deformity and the impression to which it is attributed; second, those in which there is a superficial resemblance; and, third, those in which there is an almost photographic reproduction of the mother's impression in the markings of the child."

The first class has been the one to which statistical methods have been applied chiefly. Profound grief, mental or physical shocks acting on the mother, produce

[2] Medical Classics, p. 35, 1888.

defects mentally and physically in the child. Dr. Spitzka gives the statistics of Legrand du Saulle,[1] in reference to the *ouvriers* of Paris, of the defective children born in 1871, as "enfants du siège." The French are known to be exceedingly impressionable and emotional. Of 92 children born in Paris during the siege, 64 had mental or physical anomalies, and the remaining 28 were weaklings, 21 imbecile or idiotic, and 8 showed moral obliquity or emotional insanity. The financial crises in Berlin[2] (1875 and 1880) were followed by an increased number of idiots born. Can we not see the effects of the civil war in our country? Melancholy envelops many in its dark shades. The voice of the Southern muse, which once sang so sweetly, is it not hushed? Truly has the bitterness of Rama been upon us! Observers of large experience with the illegitimate[3] say that the mental suffering of the disgraced mother reacts on them, arrests development, produces mental deficiency, or in after-years, even though under the best moral care, that offspring oftentimes follows the mother in a life of sin. The sins of the parents shall be visited on the offspring, and this law of impression the means of transmissal.

A second class, in which the resemblance is superficial and the analogy is slight. A woman[4] is angling, her playing child is finned, and the fœtal impress is outline of a fish on the sacro-lumbar region. Another,[5] severely excited, one month gone, forced to copulate by a drunken husband, seven months later gave birth to a child, which now, though fifteen years of age and possessed of common-sense, sometimes staggers and mouths his words as a drunken man. A lady,[6] three months *enceinte*, while scrubbing, was severely shocked by her husband, who from behind suddenly flaunted a large swamp-owl in her face; five months later a child was born with sharp, aquiline nose, receding chin, and very large, prominent eyes. The child, now a man, so resembles the swamp-cyclops that he is known far and wide by the appellation of "Owl-eye C." A timid, city-bred wife,[7] while pregnant, was called on to assist in disembowelling a hog. She was afterward delivered of a boy having a caudal appendix, "which, when he was in good health and flesh, would kink up, swine-like." The wife of a physician[8] discussed the pros and cons of hermaphroditismus with her husband. He also gave her some literature and illustrations on the subject. Eight months thereafter another incident occurred in the Æsculapian household which added to its census. The child had perfectly formed male genitalia, but just where the caudal extremity of the monkey is attached was a pretty fairly formed pudendency, but fortunately no cul-de-sac. The embryologist Von Baer's[9] sister carried through life a red mark on the forehead, shaped exactly like a flame. Her mother, during the last three months of pregnancy, had had this flame constantly before her. She had first seen it at a conflagration.

Under the third class a seemingly difficult phase is presented to us, yet we find many instances of almost exact reproduction of impression upon the fœtus. Dr. Reeves,[10] of Georgia, tells us of having been called in to see a patient whose hand had been severely crushed in a sorghum mill. After amputation, and before dressing, one of the patient's sisters-in-law present was requested by him to hold the stump. She was *enciente* at the time, and was eight months from date delivered of a well-developed boy, with the exception that the left hand in every particular resembled the stump. Dr. L. L. K——[11] has reported a case of "mental influence of mother on fœtus, exerted through two successive pregnancies." The shock was produced by a little daughter being severely burned by falling from a table upon a hot stove. The mother afterward gave birth to a child with the appearance of being severely burned, just like the little daughter, and it experienced like agonies. The child born in next labor was afflicted "in exact similitude to that which had caused the emotional reflex seal of the catastrophe."

The "two-headed nightingale," well known in dime-museums, was doubtless the result of a maternal impression.

Dr. B. R. Johnston[1] reports a case in which a monster was produced by a shock from the sight of the "two-headed nightingale." The patient was an X.-para. Menses ceased in March. In November she was told she was likely to have twins, whereupon she said she did "not care, so they were not Siamese." Soon after cessation of menstruation in March, she had visited the "two-headed nightingale," and fainted at the sight. Forceps and version were necessary at labor, occurring January 22d. The children were connected from neck to umbilicus. There was a common cord and common umbilicus. The connecting link was sufficiently lax to permit them to lie side by side.

Another well-known case is that of Ritta Christina, which lived eight months and eleven days.

Dr. Bechsinger,[2] of Para, Brazil, reported a case, doubtless due to an impression resulting from hypertrophy at a point where there is a natural tendency in that direction. An octoroon woman, in addition to a double vagina, had three legs. The third leg was attached to a continuation of the processus coccygeus, such as is sometimes found to a lesser degree in Sumatran Malays. The patient, who is at this time in Paris, has, besides two well-developed mammæ, a third double mamma just above the os pubis, and two vaginæ and vulvæ. Both vaginæ are well supplied with nerves, and natural pleasurable sensation is experienced in either. Sexual appetite is markedly developed. Having heard of a Frenchman who had two penes, four testicles, and three legs, she removed to Paris, France, to make his acquaintance.

The next[3] is the case reported to your honorable and distinguished body last year by the writer. The specimen is now in the hands of Dr. E. C. Spitzka, of New York, who is making researches in this field. Of the specimen, he wrote the following to the *Medical Classics:* "The case herein considered is probably the most remarkable one in the history of maternal impressions. . . . I therefore hasten to present to the same body of readers what is certainly an almost miraculous occurrence."

"Dr. W. R. Lowman, of Orangeburg, S. C., was called to attend a colored woman, living at Edisto, who presented the following history: About two months advanced in pregnancy, while passing through a copse of woods, she suddenly came upon a buzzard who, having caught a pig, had devoured the greater portion of its head. She was greatly 'shocked, mentally and bodily,' adds Dr. Lowman, and attacked with uneasy sensations in the hypogastrium. Two weeks after, these culminated in violent parturient throes. The doctor was called in at this juncture and learned the above facts. He diagnosed incipient miscarriage, which he succeeded in preventing. As soon as the woman recovered from the immediately threatening symptoms, she however discontinued the treatment recommended. One month (twenty-eight days) after this severe pains set in again, and the contents of the uterus were expelled. Fortunately Dr. Lowman was called in, and his careful examination led to the discovery of a remarkable body, which on first sight struck the doctor as resembling the body of a bird, about the size of a robin, and lacking the head. Even the skin resembled that of a plucked bird. The umbilical cord was normally attached, and the placenta, about two and a half centi-

metres in diameter, also appeared normal. Dr. Lowman adds that the feet presented a spread claw like appearance, imitating a bird's foot even to the 'subsidiary posterior digit with its long claw.' . . .

"This 'amazing freak' is in every respect a mal-developed human fœtus. The shape of the bones, where exposed; the minute character of the articulations; the disposition of the fœtal membranes, all leave no doubt on this head. As unquestionable as this fact is, it is equally indisputable that the surface resemblance to a decapitated and plucked bird is something startling. The skin everywhere, except at the points of the extremities, presents the 'goose-skin' appearance. The little papillæ contain a darker spot, whose exact nature an examination involving mutilation of the specimen could alone reveal. The neck is long, bent over, ventro-lateral, and its terminal tissues appear rounded off smoothly. At one point is seen a loose vertebral arch. From present appearances there must have been some maceration, as the end of the femur is exposed and the left leg is distorted upward; probably through the expelling force of the uterus. The upper extremities terminate at the distal humeral end, which is covered by a membrane continuous with the subcutaneous tissues. At one place the cutis is raised from the right arm. The disposition of the thighs and legs is marvellously bird-like, particularly in the contour of the muscular masses. The feet are human feet, exhibiting a tendency to webbing of the toes, of division beyond the metacarpo phalangal line, and on the left foot, most remarkably, a claw, set back as in the bird's! The dorsum is prolonged into a caudal process, repeating the disposition of a bird's. I reserve a more detailed analysis till I can accompany it by more exact delineations. [This will soon appear in *Medical Classics*.—W. R. L.] Provisionally, I would say that this case fulfils one condition demanded by Hunter and Darwin, and demanded in vain, *i.e.*, the woman related her impression before the fœtus was delivered. Its explanation is therefore not an after-thought. A most interesting speculation may be indulged in regarding the unconscious psychological process and impression which combined the impression of the bird, which had its head, with the headless character of the pig. It may be also questioned whether the—to a woman—familiar figure of a plucked bird was superadded. The chest exactly resembles a robin's breast. Certainly, as a whole, the resemblance externally to a bird is so great that before the days of comparative anatomy and embryology superstition would have undoubtedly found much food in this specimen. Dr. Lowman's case now offers to us a valuable and unimpeachable permanent record of a maternal impression."

And what adds to the peculiar interest and value of this case is the fact that in the next pregnancy of this same woman a completely analogous incident occurred, except that when the woman aborted (March) she was further advanced. The fœtus must have been dead in utero for two weeks or more before the mass was expelled. Decomposition was considerably advanced, and the fœtus was crushed and macerated. Still, the fragments examined presented almost exactly the contourage of the first result of the impression, and some parts, particularly the feet, were in a much higher state of development. The legs were very similar to those of a vulture. This specimen, although much decomposed, is still in a preservative fluid in my office, and while it is inferior to the first as a specimen, yet it is of great value since it shows the consecutive influence of the "emotional reflex seal."

The last case to which I will refer is that of an amelus, or limbless monster, reported by Dr. R. T. Cæsar, in the *British Medical Journal*, March 9th. He says: "I have in my possession a specimen, which was born at full term, and consists of a head and trunk fully developed, but no trace whatever of a limb, no appearance of intra-uterine amputation having taken place; no scapula or clavicles, and no acetabula, simply a fully developed male trunk. Fifteen months before the birth of this child I was summoned one morning by a midwife to attend the mother in her fourth confinement. On my arrival at the house I found an arm born, and the nurse holding on to it with all her strength, trying to bring the child into the world in this way, and this she had been doing for some hours. As may be imagined, the child was so firmly fixed in the pelvis that I found it impossible to move it, even under the influence of chloroform, nor could my friend, Dr. Young; so, in the end, we were obliged to eviscerate by opening the thorax in the axilla, amputating the arm, and delivering with forceps. The child, of course, had been dead some time. When all was over, and our backs turned, the stupid nurse allowed the mother to see the mutilated remains, which considerably shocked her. Fifteen months after, she was delivered of the subject of this note. How far we can call this a case of maternal impression I will leave your readers to decide."

IV. In view of all the facts adduced above, would it not behoove us, in behalf of ourselves, in behalf of our country, in behalf of the human race, to advise together for means of treatment? And there being nothing applicable save prevention, should there not be some law to enforce legal hygiene in this particular direction? Plato, in the "Seventh Book of Laws," after discussing how easily impressions are stamped upon newly born infants, says: "Nay, more, if I were not afraid of appearing ridiculous, I would say that a woman during her year of pregnancy should of all women be most carefully tended, and kept from violent or excessive pleasures and pains; and, at that time, she should cultivate gentleness, benevolence, and kindness." It seems that mediæval legislation was in some instances more enlightened than that of to-day. Our authorities "allow horrifying pictures of museum freaks to be placarded all over town, thus risking the production of numerous deformities." While Bavaria[1] banished "a maid with two heads" from her limits, "lest that by frequent looking upon her the imagination of women with child, strongly moved, should make the like impression in the infants" they bore in their wombs, the Roman aristocrats[2] recognized the law of maternal impressions and considered their wives sacred during the first months of pregnancy. It is certain that the mind is more susceptible at this time to impressions. The Romans therefore jealously guarded their wives against external mal-impressions of a shocking character at such times, and surrounded them during the whole period with beautiful objects and agreeable sights and sounds. The result is well known. We have as their progeny a race of high artistic development, which has given birth to many like Michael Angelo and Patti. Nor could I better conclude this *résumé* than again to say:[3] "Let us consider these things, although they be seemingly unscientific, before we enter our final *nolle prosequi* upon them. There are many things and mysteries occult in nature's breast, of which we know not the *modus operandi*. The story of Minotaur, his savage lusts and escapades, and final overthrow by Theseus, is not, at least in theory, all a myth. And although the progressing enlightenment of the mind has already swept away, as was it a fate deserved, the belief in 'spooks,' mesmerism, spiritualism, 'equivocal generation,' zoöspermes, the supernatural power of bezoar, the exaggerated idea of the influence of the moon, and many errors of like kind, yet this fate is not in store for the influence of maternal impressions during gestation. 'Tis true—'tis no error—'tis no delusion. *Magna est veritas, et prævalebit.*"

## SOME POINTS IN THE TREATMENT OF GONORRHŒA.

By BRANSFORD LEWIS, M.D.,

ST. LOUIS, MO.

In The Medical Record of July 20th Dr. E. P. Rice describes a method of treating gonorrhœa which has given him much satisfaction.

In the first place, believing in the theory that gonorrhœa is due to a specific microbe, the gonococcus, he advises the antiseptic plan of treatment. In order to carry this out, he inserts into the urethra, as far back as the prostatic portion, a soft rubber catheter; through this, by means of a glass syringe which he attaches to the distal end of the catheter, he injects two drachms of the following emulsion: Ac. boric., ʒ iij.; glycerine, ʒ j.; and hopes to see five or six treatments suffice to attain a cure.

There are some points in the above to which I would beg leave to take exception.

In the first place, to deposit two drachms of any fluid in the prostatic urethra would almost assuredly defeat the primal object of the operator—that of spreading his application over the portion of the urethra that is inflamed; for the muscular structures surrounding the urethra are so arranged that, at the triangular ligament, they divide the canal into two parts, the anterior and posterior urethra. That this division is real, physiological as well as anatomical, and not merely arbitrary, and for the sake of making finer but impractical distinctions, may be demonstrated in various ways, one being the very fact that, if we inject a quantity of water, say a quart, through a catheter whose eye is just distal to the triangular ligament, that same amount will return alongside the catheter and escape at the meatus; whereas, if we place the eye of the catheter just beyond (proximal to) this muscular ring, and then inject, the fluid will not reappear at the meatus, but will pass on into the bladder. Indeed this is the mode of irrigating the posterior urethra originated and practised by the recently deceased Ultzmann in chronic posterior urethritis. So, therefore, the bulk of the two drachms (aside from what has remained within the catheter) used by Dr. Rice, probably exercises its effect on the mucous membranes of the posterior urethra and bladder, and all that reaches the inflamed area does so by following in the track of the catheter as it is being withdrawn.

It has been determined[1] that the natural rate of progress of the gonococci, as they invade the tissues from the meatus backward, is notably a slow one; that, unless carried back by some accident or instrumentation, they do not reach the bulbo-membranous neighborhood until about the third or fourth week of the disease; and, furthermore, that it is only a minority of the cases in which the posterior urethra is involved at all, being preserved from this by the musculo-membranous barrier before mentioned.

It will be readily conceded, of course, that to treat any portion not involved in the inflammation is nothing short of "meddlesome surgery," aside from the risks, to which it leads, of infecting innocent tissues. So that the corollary of the above premises would lead us:

1st. To refrain from passing our instrument to even the deeper portion of the anterior urethra, in the early stages of the affection; and,

2d. Never to pass it beyond the compressor urethræ muscle, unless the posterior urethra be affected—which is always shown by well-defined symptoms.

Another question comes up: Is glycerine the best vehicle we can use in making our antiseptic emulsion? From its hygroscopic nature and rubefacient effect, is it not likely to be irritating, rather than soothing, to the raw and tender membrane? And again, in the presence of water glycerine loses entirely its lubricous properties; with the first urination out it goes, and the medicament with it, so that, until the next treatment, the membrane is minus the beneficent influence of the antiseptic.

None of these objections applies to vaseline or lanolin. They are perfectly bland and unirritating, giving rise, because of their presence, to absolutely no pain or irritation, but, on the contrary, mollifying that which already exists, by keeping the inflamed surfaces from rubbing against one another, and also, by the coating which they form, preventing the scalding contact of the urine. Water has little or no effect on them, so that they are persistent and adhere to the canal-wall even after several urinations; this assures the continuous application of the remedy, as well as of the protecting vehicle, and obviates frequent repetition of the treatment.

Of the two, vaseline and lanolin, the latter, in my estimation, is preferable. It is a far more elegant preparation; is more readily absorbable, carrying with it into the subepithelial layers, the stronghold of the cocci, the germicide with which it is charged; and lanolin is antiseptic in itself.

As a means of introducing this preparation I have been using an application as suggested by a Dr. Smith, of England, a year or so ago. It is simply a hard-rubber rectal ointment-applicator, modified by having a catheter-end, four or five inches long, which may be inserted into the urethra to any depth desired; the screw-piston serving to express the ointment at the proper time.

Boric acid is doubtless an excellent remedy, it fulfils two essential requirements: it is antiseptic and at the same time unirritating. I have been in the habit of using resorcin, three to four per cent., to which, in the later and subacute stages, I add some antiseptic astringent, such as the sulpho-carbolate of zinc.

With this plan as a basis, and the addition of hygienic and rational adjuvants, results have been more encouraging than with any other method with which I am conversant.

## INTESTINAL OBSTRUCTION OVERCOME BY THE PASSAGE OF A RECTAL TUBE.

By PHILIP F. O'HANLON, M.D.,

NEW YORK.

Having read in The Medical Record of August 3d an article by Dr. DeWitt C. Rodenhurst, on intestinal obstruction, I would like to relate my experience. During my service as House Surgeon of Gouverneur Hospital a man about fifty years of age was admitted to the ward. His abdomen was distended and filled with gas, he was suffering most intense agony; had had no movement from his bowels for a week, was vomiting, and was unable to sleep owing to pain. Intussusception was diagnosed, and enemas of soap water and turpentine were given, the injection being repeated five or six times with no result. A gas stove was on the table, to which was attached an ordinary rubber tube of about the diameter of the little finger. I cut off thirty-six inches of this tube, vaselined it well, put the nozzle of a syringe at the end of the tube, and passed the other end into the man's rectum, distended the rectum with water, and screwed the tube toward the sigmoid flexure. But the tube would not advance, and then I inserted one finger, then two, and gradually distended the anus until I got my right hand within the rectum, grasping the tube with my fingers, and after a screwing motion had been continued for a few minutes suddenly the tube advanced and made onward movement until thirty inches had passed. I was startled by one of the staff stating that I had probably perforated the gut and gone into the peritoneal cavity; at the same time I felt that so long as I had gone so far I might as well finish what I intended doing, namely, to overcome the intussusception. I pumped about

four quarts of water through the tube, when suddenly a puff of gas escaped per rectum, and the man's abdomen began to sink. With a cry of joy the poor fellow kissed my hand and manifested his gratitude in other ways. What happened in this case was this: The smaller intestine had been pushed out of the larger one by the distention of the water that had passed through the tube, thus allowing the escape of the small intestine from the large. The tube was felt without any trouble in the ascending and transverse portions of the colon, the man being thin and having little fat on his abdomen. I did this in three cases in the hospital, two of which were successful; the third case was diagnosed intussusception, and failing, the visiting surgeon was notified, and after a careful examination it was decided that laparotomy was the patient's only chance. The operation was performed by Dr. H. M. Silver, and it was found that adhesive peritonitis was the cause of his trouble.

I write this because it has been said that the tube could not be passed so far along the intestine, and I trust that the report of these cases may be of use to those who doubt the value of the method.

## SATYRIASIS CAUSED BY VARICOCELE, AND CEASING AFTER SUCCESSFUL OPERATION FOR THE LATTER.

By GEORGE T. WELCH, M.D.,

KEYPORT, N. J.

In August, 1888, a young German, of a slender but lithe and vigorous physique, consulted me in regard to an aggravated eruption of tinea versicolor, from which I found he suffered more agonies of mind than of body, the unpardonable error of diagnosing the disease as syphilis having been committed by his previous medical advisers. A cure speedily followed upon the use of proper epidermicides, and I so won the patient's confidence that he, with much embarrassment, proceeded to divulge a far more serious difficulty, and ventured to hope for relief from this also. He informed me that he had had for four years an inordinate passion for the opposite sex, which had so tormented him that he had felt it incumbent upon him to keep away from the presence of women, lest he should commit some flagrant outrage, or at least betray his emotions in some unguarded moment.

He had lascivious dreams, and like Rousseau he had reveries in which the women of his acquaintance accorded him the last honor of exalted pleasures. The rustle of a silken dress would stir fancies in him too lawless for expression, and he would doubtless have given way to an erotic mania had he not had good sense at the bottom of these mischievous desires. He had reasoned with himself, and had come to the conclusion that some disease prompted the morbid symptoms, and he had attributed them to an enlargement of the left testicle, which he did not understand.

He told me he had used cold douches to the genitalia, had made frequent use of Turkish baths, light diet, abstinence from liquors, avoidance of the sex and of stimulating literature and pictures, but all to no purpose, and shame had prevented him from consulting a physician in regard to the matter. So cool an analysis of his own symptoms precluded any suspicion of mental disease, and there was no reason to suspect any phase of epilepsy.

I at once proceeded to examine the condition of the testicle referred to, and found an enormous varicocele—the largest I had ever seen. The enlarged veins hung below the testicle, and I was informed that under the stimulus of sexual desire the veins became even more extended than I then saw them. Without promising relief from his satyriasis, though I encouraged him to hope for it, I advised an operation for the cure of the varicocele, at once, to which he willingly consented.

Having made his arrangements to retire from business for a fortnight, I operated on him the following day. I separated the varicose veins from the vas deferens while the patient was standing, and the veins, therefore, more completely distended; but warned by Mr. Jacobson's disastrous experience in a similar case, where gangrene followed upon ligating too many of the veins, I left a small number of them undisturbed. The scrotum was then transfixed behind the separated veins with a scalpel, and the veins ligated with carbolized catgut ligature in two places, an eighth of an inch apart. The ends of the ligatures were cut off, and the latter were thrust back into the scrotum, a dressing of carbolized cotton completing the operation. A good recovery was made, and I am pleased to say the excessive sexual desire diminished from that time on, to the intense satisfaction of the patient. He resumed the social life he had longed for, without any return of the morbid symptoms.

## A CASE OF BLOODLESS LABOR.

Dr. B. J. Wetherby, of Arlington, Kan., writes: "On July 17, 1889, I was called to confine Mrs. C——, aged thirty. She had previously given birth to four healthy children, the births being unattended by anything out of the usual order. After about two hours of waiting and a little assistance a healthy, well-nourished male child was born. As soon as the cord ceased to pulsate I put two ligatures around it, as I always do, and cut the cord between them. In about ten minutes uterine contractions came on and the placenta was expelled without any assistance on my part. As I transferred the after-birth to the vessel, I was surprised to find that my hand did not have a single blood-stain upon it; and upon further investigation I found that not a single drop of blood had been lost except that resulting from cutting the cord. The patient stated that after her previous confinements she had suffered terribly from after-pains, but I hazarded the assurance that in this case she would suffer little, if any. When I saw her next day she told me she had had no after-pains at all, and I found that no clots had been expelled. The woman made a rapid recovery. Several physicians have made the statement that an entirely bloodless labor is impossible, therefore I report this case.

"There is some difference of opinion as to the proper management of the third stage of labor, some advising active expression of the placenta, while others advise the expectant plan. The point of difference is principally in regard to the method of separation of the placenta, the advocates of the Credé method of expressing the after-birth holding that separation begins at the edges, while the opponents of the method claim that separation is effected by the formation of a retro-placental hæmatoma. If the latter theory is correct how was the placenta separated in the case I have just recorded, when there was no hæmatoma, retro-, intra-, or extra-placental? I have no theory to offer, but simply state the case as I saw it. The Credé method, properly performed, is good enough for me."

A Cautious Britisher.—In a paper on the change of gray hair to black by the use of jaborandi, published in the *Therapeutic Gazette*, Dr. Prentiss relates that a previous case reported by him had been commented upon by one of the New York dailies, the result of which was an avalanche of letters from people asking for information and offering money for the recipe. One man in England wrote, enclosing the half of a two-dollar bill, with the information that the other half would be sent at once upon receipt of the formula.

Tincture of Iodine Internally for Warts.—Dr. Imossi, writing in the *Bulletin Général de Thérapeutique* of June 15, 1889, recommends the employment internally of tincture of iodine in the treatment of warts. He has obtained excellent results in a number of cases with this remedy, in doses of ten drops twice a day for adults.

THE MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

**New York, August 17, 1889.**

## PREVENTIVE INOCULATION AND THE THEORY OF ITS ACTION.

OF all the questions that have been brought to the notice of the medical world in recent years, none has been the subject of more acrimonious discussion than that of Pasteur's alleged preventive inoculation for rabies. Yet we venture to say that many, even of those who have taken part in the discussion, have but a very hazy conception of the theory upon which Pasteur bases his methods. This theory was set forth in a very able and interesting manner by M. Roux, in the Croonian Lecture recently delivered before the Royal Society.

Preventive inoculations were first used, the speaker said, for variola, but they had now been superseded by vaccination. A more satisfactory method of preventive inoculation had been furnished by the discovery of the power of artificially attenuating (weakening) virus.

It was in studying "chicken cholera" that Pasteur first obtained cultures of an attenuated virus. The gradual diminution in the virulence of the virus was found to be due to the action of the oxygen of the air. If, instead of making the cultivation in a bottle, where the renewal of the air was possible, we were to make it in a closed tube containing only a small quantity of air, the microbe would soon consume all the oxygen, and would cease to grow, for oxygen was a necessity of its development. In a tube deprived of air it could not grow, but it remained alive for a long time, as one could satisfy one's self by sowing in aërated *bouillon* the small culture formed in the sealed tubes. After being thus preserved for a year it gave cultures which were as active as a recent culture from the blood of a fowl just dead of chicken cholera. The diminution in virulence which took place in cultures exposed to the air was therefore dependent on that exposure, and not on the length of time the microbe was kept.

In applying this method to the virus of splenic fever a difficulty arose. It was found that the spores formed during the first hours of culture were able to resist the action of the oxygen of the air. To prevent the bacilli from producing spores, the virus must be cultivated at a temperature, not of 35° C., as in the case of the virus of chicken cholera, but at one of 42° to 43° C. Under these conditions the bacilli developed, producing the filaments, but no spores. By drawing off every day a little of the culture from the bottle at 42° and placing it in *bouillon* at 85° C., we had a series of cultures of graduated virulence, and furnished with spores capable of fixing each of these special degrees of intensity. The preventive vaccination of sheep had reduced the mortality from splenic fever to one per cent. If in nature we came across one of those attenuated bacteria we had learned to prepare, and which were so harmless as to be incapable of killing even a mouse, it would clearly be impossible for us to recognize in it a descendant of the terrible *bacillus anthracis*. To do so it would be necessary to have watched it in its stages of gradual attenuation. But it was possible (unless the process of attenuation had been carried too far) to make the bacillus reascend the steps of virulence. It was not capable of killing even a mouse. But let us inoculate with it a very young mouse, only one day old. This young mouse would be much more sensitive than an adult mouse, and would die in a few days. In developing in this young mouse the bacillus would recover a portion of its old fitness for life in living surroundings. The blood of this first mouse introduced into that of one a little older, would cause its death, and thus proceeding step by step from the youngest mouse to the oldest, it would gain power to kill first old mice, then guinea-pigs, rabbits, sheep, and, last of all, oxen.

M. Roux then referred to *rouget*, and to an extraordinary point in connection with it, discovered by MM. Pasteur and Thuillier. By passing the virus through a number of rabbits in succession it could be rendered more potent, but as the strength of the virus increased for the rabbit it was diminished for the pig; so much so that, after a sufficient number of passages of the virus had been made through the rabbit, it had become a vaccine for swine, able to confer upon them exemption from the fatal form of malady. With this example before us the question arose, What would happen with certain human diseases if we made them also pass through a great number of different kinds of animals? Was not this very process taking place in nature, and did it not give fresh support to the idea that the vaccine of small-pox became modified by its passage through the horse and the cow?

The lecturer then proceeded to discuss at some length Pasteur's work in regard to rabies. M. Pasteur, he said, had demonstrated that the true seat of the virus was to be found in the nervous system, and that by inoculating the virus directly into the nervous system the incubation period could be shortened. If inoculation by trephining (with antiseptic precautions) were performed upon a series of rabbits from the spinal cord or medulla of an animal just dead, and this process were continued with successive animals, we found that the incubation period, at first fourteen to eighteen days, gradually diminished. It became shorter and shorter, until it finally went down to six days. At that point it remained stationary, and the rabic virus was said to be fixed, it having attained its maximum virulence for that animal. The virus was attenuated by gradually drying in pure warm air (at 25° C.) the spinal cord from a rabbit which had served in a passage series of inoculations, and therefore contained "fixed" virus. At the end of fourteen days this spinal cord was absolutely innocuous, after having passed down the scale of gradually diminishing activity during the preceding days. Having now obtained our material containing the attenuated virus, if we each day injected subcutan-

eously into a dog a portion of the attenuated cord, crushed in water, beginning with the harmless fourteen days cord, then going on day by day till we reached the cord at zero, or, in other words, spinal cord unattenuated, spinal cord which was deadly, the dog thus inoculated would not die. He would even remain well if the most active rabic virus were inoculated into his brain, though we knew that otherwise intra-cranial inoculation produced rabies without fail. The exempt condition had been obtained in one fortnight. As rabies usually remained latent in a dog which had been bitten for a period generally exceeding one month, it was thought that it might be possible to profit by the long exemption period to give exemption from the malady before its manifestation. Experiments on dogs showed that this could be done, and since then the method had been applied to man. The circumstances under which the latter step had been taken by M. Pasteur were now a matter of history.

M. Roux then proceeded to speak of the poisonous products manufactured by microbes, and the way in which they could be utilized for protective vaccinations. By introducing, little by little, into the bodies of animals those chemical substances produced by pathogenic microbes (*e.g.*, those of acute septicæmia), in such a manner as to avoid causing speedy poisoning, but so as to gradually accustom the animal to their presence, it became refractory not only to toxic doses which would have originally caused death, but also even to the microbe itself. Besides the chemical, we had also the physiological question to deal with, as shown by the fact that, although the rabbit was by nature refractory to "quarter evil," yet, inoculated with the virus after having first had a lesion produced in its tissues, an anthrax tumor would soon appear, and the animal might succumb. When an active virus was injected into a refractory animal the microbes were soon destroyed—chiefly by the phagocytes. Any satisfactory explanation of the problem of immunity should comprise these facts, and be based upon the relative importance of the action of the chemical products and the resistance of the tissues. The lecturer remarked that the best explanation was to consider immunity as the result of the habituation of the cells to the poisons secreted by the microbes.

## THE DIETETIC TREATMENT OF GOUT.

An interesting confirmation of the views expressed for a long time by certain American physicians, notably Dr. Wm. H. Draper, regarding the dietetic treatment of gout, may be found in a paper recently read before the Congress of Internal Medicine by Professor Pfeiffer.

No particularly new views are entertained on the subject of the pathology of this affection, and, indeed, nearly all views are still to be reduced eventually to a question of uric acid.

"The first indication," he says, "in treatment (*Medical Press and Circular*) should be the excretion of a proper amount of urea and uric acid in the urine, since the retention of this product soon produces a low cachectic condition of the system. After this, the administration of a salt that will convert the insoluble substance into a soluble substance allowing of rapid elimination, soon relieves the pain and reduces the swelling. The first important step is to correct the diet. This should consist largely of albuminous matter, as beef, eggs, etc., as well as fat and green vegetables; but fermented drinks, starch, and sugar should be forbidden. The use of a meat diet is very important, as the retention of the urea and uric acid quickly produces a cachectic condition of the system which must be early combated in the treatment; but the meat diet does more than supply this necessity, for the salts of the meat, when taken into the system, have a solvent influence that speedily raises the elimination of urea and uric acid to even more than the normal quantity. The same may be said of all proteid substances, and more particularly of eggs. Sour milk and cheese should be avoided, but fruit and salads are beneficial, as they alkalize the alimentary canal; while wine and beer have the opposite effect, and should be strictly prohibited.

"The medicinal treatment should consist in the administration of some alkaline salt, and the carbon salts seem to be the best, though phosphoric acid and boracic acid have, in some cases, proved beneficial. Hydrochloric acid and sulphuric acid are objectionable. All alkaline and mineral waters should be given in small doses to begin with, and gradually increased."

Certain German mineral waters and baths are, of course, very highly recommended.

The formal advocacy of a meat diet, however, shows that physicians generally are breaking away from the canonical teachings of the English school.

It is not to be forgotten, however, that there are many cases of gout, especially in very plethoric persons, in which meat is not tolerated.

## POST-MORTEM SWEATING.

This curious phenomenon is said to have been observed occasionally in cases of sudden death in acute disease, and is supposed to be due to the continuance of capillary circulation for a brief period. But a case related by Dr. J. A. Cones in *The Lancet* of May 25, 1889, appears to be unique in the length of time that had elapsed after death before the transudation through the skin occurred.

The patient had albuminuria, without dropsy or ascites, and ten days before his death was seized with uræmic coma, in which condition he remained to the end. During the last forty-eight hours of his life, and even at the moment of his death, he was perspiring freely. The body was washed and laid out on a bed, and four hours later was placed in the bier. At this time nothing unusual was noticed. But the following morning the sheets and pillow on which the body lay were saturated with moisture, and the skin was cold and wet. This exudation continued for about eight hours, and then ceased.

The theory of a continued capillary circulation will not suffice in explanation of this case, for there was no sweating immediately after death, and it did not begin until several hours later. The author suggests that it was the result of compression of the sweat-glands and surrounding lymph-spaces taking place when rigor mortis began. The man had been sweating profusely at the time of his death, so that it would be not inapt to compare the surface of his body to a large sponge which yielded its fluid upon being squeezed. That the man was actually dead was shown by the fact of post-mortem discoloration, which was well marked when the body was first seen on the morning after death.

# News of the Week.

ANOTHER IMPOSTOR.—A correspondent sends the following note of warning concerning a man who has already victimized a number of charitably disposed persons in this city: "A physician holding a diploma from Bellevue Hospital Medical College, and bearing a paper signed by a number of persons alleged to be physicians in Johnstown, Pa., stating that he is a victim of the great disaster, has been applying to graduates and professors of Bellevue College, and probably to other physicians, for aid to establish himself in Troy, N. Y. He gives as reference a gentleman of Troy doing business as a brewer. A note just received from the gentleman denies all knowledge of the man. Evidently, we have to do with a fraud. Mendacity combined with mendicity is doubly criminal, because besides the direct wrong it poisons the fountains of sweet charity."

THE FRENCH SURGICAL CONGRESS.—The fourth session of the French Congress of Surgery will be held in Paris, in the grand amphitheatre of the Ecole de Médecine, on October 14 to 20, 1889. The President of the Congress is Baron Larrey. The following are the subjects announced for discussion: 1. The immediate and remote results of operations for local tubercular troubles. 2. The surgical treatment of peritonitis. 3. The treatment of aneurisms of the extremities. The remaining sessions of the Congress will be occupied with the reading of voluntary communications and the presentation of patients and apparatus. All communications relating to the scientific business of the Congress should be addressed to the Secretary General, M. Pozzi, No. 10 Place Vendôme, Paris.

DR. MARY E. HANCHETT died recently in Chittenango, N. Y. She was graduated from the Albany Medical College in 1848, and was one of the first women to receive a degree of doctor of medicine in this country.

CONVICTION OF AN INSURANCE EXAMINER.—A physician in Belfast was recently sentenced to six months imprisonment for having passed as sound an applicant for insurance who was suffering at the time with well-marked cardiac disease and dropsy, and who died shortly afterward.

INJECTIONS OF TESTICULAR JUICE.—The Brown-Séquard trouble has struck America, and seems to have at once attained the proportions of an epidemic. The daily papers are filled with reports of testicular injections practised all over the country, and on old men in all stages of decrepitude. The results in each case, if the despatches are to be believed, are little short of miraculous. One of our German exchanges, in commenting upon the rejuvenator, remarks that it furnishes additional proof of the wisdom of retiring professors at the age of seventy. Brown-Séquard is seventy-two years of age.

"THE WESTERN MEDICAL AND SURGICAL REPORTER" is the name of the latest born of medical journals in this great country. The object of its creation is stated to be to give the Western doctor and the Western medical school a show. We, of the effete East, greet our Western brother and wish him every success in his laudable undertaking.

A SOCIETY OF HYGIENE AND PUBLIC HEALTH has recently been founded in Rome.

DR. N. SENN has been proposed for honorary membership in the National Academy of Medicine of Mexico.

THE NEW JERSEY STATE VETERINARY MEDICAL ASSOCIATION held its annual meeting in Hoboken on August 9th. Secretary of Agriculture Rusk, Mr. Philip, Chief Clerk of the United States Bureau of Animal Industry, and Franklyn Deyo, Secretary of the State Board of Agriculture, were elected honorary members.

THE AMERICAN PUBLIC HEALTH ASSOCIATION will hold its seventeenth annual meeting in Brooklyn, on October 22 to 25, 1889. The programme is a very extensive one, and includes discussions on yellow fever, diphtheria, tuberculosis, compulsory vaccination, prison, railway, and steamship sanitation, methods of scientific cooking, etc.

MR. CLARK BELL, President of the Medico-Legal Society of this city, was entertained at a reception by the President and Council of the London Society for the Study of Inebriety on July 26th, in the rooms of the Medical Society of London. Several resolutions were passed and speeches made complimentary to the Medico-Legal Society and to its President.

DR. PAUL MEYER, Privatdocent of Strasburg, and for a number of years assistant to v. Recklinghausen and Kussmaul, died recently of endocarditis, at the age of thirty-six years. He was known to many Americans, who will be pained to learn of his early decease.

A COMPLETE SET OF THE TRANSACTIONS OF THE CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS, said to be the only copy in existence, came near being captured by America. It was offered for sale, and was on the point of being sold to an American, when a member of the Society stepped in and purchased it at a high price.

DR. OSCAR C. DE WOLF has resigned his position as Health Commissioner of Chicago, after a continuous service of thirteen years. Dr. Wickersham has been appointed his successor.

THE AMERICAN ACADEMY OF MEDICINE will hold its next annual meeting in Chicago, Ill., on September 17 and 18, 1889.

THE MEDICAL SOCIETY OF VIRGINIA will hold its twentieth annual meeting on September 3 and 4, 1889, at Roanoke, under the presidency of Dr. E. W. Rowe.

SUICIDE OF PROFESSOR LORETA.—Professor Pietro Loreta, of Bologna, by whose name the operations of resection of the liver and digital divulsion of the orifices of the stomach are known, killed himself with a razor on July 19th. He had lately shown symptoms of melancholia, and had several times suggested to his friends the desirability of putting an end to the persecutions to which he believed he was exposed, by taking his own life. Loreta was born in Ravenna, and was fifty-eight years of age at the time of his death. Last spring two tablets were erected in Bologna commemorating the "Loreta operations," and the distinguished surgeon was the recipient of many honors, at the time, from societies in Europe and America. Until his mind became diseased he was always of a happy and cheerful disposition.

THE DECADENCE OF THE CIGARETTE.—The falling off in the habit of cigarette smoking, at least in the street and other public places, is becoming very noticeable, and dealers also say that there has been of late a very great decrease in the sale of cigarettes.

A DEATH AFTER THE ADMINISTRATION OF SULPHONAL.—A case is reported by Dr. R. R. Petitt, in the *Medical News*, in which death followed the exhibition of thirty grains of sulphonal. The patient was a woman aged twenty-eight, and the drug was given in two doses of fifteen grains each, with an interval of an hour and a quarter between them.

A REGISTRATION LAW IN NORTH CAROLINA.—The law relating to medical practice, recently passed in North Carolina, requires that every person entitled to practise medicine in that State shall register in the office of the Clerk of the Superior Court of his county, before January 1, 1890. The first license under the new law was issued to Dr. Thomas F. Wood, editor of the North Carolina *Medical Journal*, of Wilmington.

THE AMERICAN SOCIETY OF MICROSCOPISTS will hold its thirteenth annual meeting in Buffalo, on August 20th.

THE MEDICAL JOURNAL TRUST.—This is the way the funny rumor about a medical journal trust has affected one of our esteemed contemporaries. Under the caption of "An Infamous Scheme," he writes: "On the eve of going to press we are pained at a current report purporting that a general move is on foot to form a mammoth 'Medical Journal Trust;' whereby Meritorious Journals may be crushed out of existence by a combination of prominent proprietary and patent medicine houses. This combination is said to be known as the 'American Medical Press Association.' This move, if not thwarted at once, will aim directly at the complete annihilation of every legitimate medical journal in the United States; their places being filled by trade and patent medicine journals. Let the physicians of this country keep a critical eye on this hydra-headed monster. The plan for destruction seems to be to induce all advertisers to gradually withdraw their patronage from the reliable medical journals, and place them in the hands of trade and patent medicine journals; thereby causing good journals to die out for want of support. Unless this infamous trick is exposed, and every physician does his duty, patent medicine humbugs will drive to the wall the physicians of the whole country. Let the physicians of the Southwest sit down on this dastardly scheme in no uncertain manner. Let the wolf in sheep's clothing be jugulated before it envelops with its slimy embrace every legitimate interest of scientific medicine." We think the writer is somewhat needlessly alarmed, for this alleged trust is, we opine, largely a creature of the imagination.

THE CONDITION OF THE MEDICAL PROFESSION IN GERMANY.—In an address to a German medical society Dr. Hüllmann, of Halle, discusses the ever-interesting theme of the state of the profession and the outlook for the future, which in Germany is no more promising than it appears to be in this country. The main causes accounting for the unsatisfactory position in which medical men find themselves are, he considers: (1) The increase in the number of practitioners as compared with that of the population; (2) the low remuneration offered by clubs, and the competition for appointments which bring in but little more than the pay of an artisan; and (3) the continued development of specialism. He goes on to show that there has been a steady increase in the proportion of practitioners to population—from 3.33 for each 10,000 in 1883 to 3.77 for each 10,000 in 1888. The remedies he suggests are to limit the number of men entering the profession, and also the number of specialists. He remarks that at present the course for the medical student is shorter than that for students of any other learned profession, for only four years are obligatory; while a lawyer has, in addition to his three and a half years' study at the university, to spend an equal period in learning the practical duties of his profession; a pastor has, after his university general studies, to spend two or three years as "Candidat;" and a school-master must after his university course work for a probationary year before he can obtain the grade of assistant master. Considering the immense amount of scientific knowledge that a medical man ought to acquire, five years would, in his opinion, seem to be the very least that ought to be enjoined, and if a knowledge of mental diseases and hygiene is to be attained, a longer period will be necessary.

ALBOLENE.—In an article in THE MEDICAL RECORD of July 6th, page 23, referring to a paper on "Menthol in Laryngeal Phthisis," by Dr. Charles H. Knight, it should read that the drug was dissolved in fluid albolene, not "fluid cosmolene," as printed.

## Reviews and Notices of Books.

PHTHISIE LARYNGÉE. Par le DR. A. GOUGENHEIM, Médecin de l'Hôpital Lariboisière et de la Clinique Laryngologique de l'Hôpital Lariboisière, et PAUL TISSIER, Interne des Hôpitaux de Paris. Paris: G. Masson. 1889.

THIS work on laryngeal phthisis fills a gap in medical literature, for such an exhaustive treatise on the subject has not appeared in many years. The author's reputation is a guarantee in itself of the reliability of the work. The book is illustrated with woodcuts, and several chromolithographic plates.

DU LAVAGE DE LA VESSIE SANS SONDE. Par le DOCTEUR J.-M. LAVAUX, Ancien Interne des Hôpitaux de Paris, Membre de la Société de Médecine Pratique. Paris: G. Steinheil. 1888.

IN this monograph Dr. Lavaux describes in detail his method of washing out the bladder without the use of a sound, indicates its uses, and especially its value in the treatment of cystitis accompanied with much pain. A number of cases are reported to show the range of applicability of the method.

GUIDE TO THERAPEUTICS AND MATERIA MEDICA. By ROBERT FARQUHARSON, M.P., M.D. Edin. Fourth American Edition. By FRANK WOODBURY, A.M., M.D. 12mo, pp. 598. Philadelphia: Lea Brothers & Co. 1889.

THIS work is probably the most complete and comprehensive of its kind that can be found. To the practical therapeutist it is almost invaluable, giving as it does in the smallest possible compass the latest and best means in the shape of drugs for the treatment of all classes of disease. The talented American editor has made some very important additions which particularly adapt the handbook to the wants of the American practitioner. As he aptly styles it, it is "a miniature dispensatory."

ATLAS OF VENEREAL AND SKIN DISEASES. By PRINCE A. MORROW, A.M., M.D., Clinical Professor of Venereal Diseases; formerly Clinical Lecturer on Dermatology in the University of the City of New York; Surgeon to Charity Hospital, etc. New York: William Wood & Co. 1889.

THE "Atlas of Venereal and Skin Diseases," by Dr. Prince A. Morrow, of which notices have appeared from time to time, is now complete, and forms the most valuable and comprehensive addition to the literature of this branch of medicine that has yet appeared in any language. The illustrations are marvels of artistic excellence and clinical accuracy, and altogether form a collection of typical skin lesions the value of which to the student and practitioner can scarcely be estimated. The study of skin diseases by mere text-books has always proved uninteresting, simply for the reason that, no matter how accurate the word-description may be, there is no lasting impression made upon the mind of the learner, but rather a confused notion of form, color, and general characters of an eruption. The picture of these diseases can never be complete until it is actually presented to the eye as it appears upon the patient, with form, color, general arrangement, situation, and distribution, such as can be seen in our large cliniques in skin diseases. Next in order is the faithful and artistic presentation in plates, such as are contained in the plates which make up this truly remarkable collection. The illustrations of the different forms of syphilis, extending as they do over the whole range of this interesting and common disease, gives a range to the study which is almost surprising. The typical forms of other skin lesions are also admirable in their way, and leave nothing to be desired in the presentation of the salient points of study for the rarer as well as simpler forms.

Dr. Morrow, the painstaking author, has placed every student and practitioner under obligations to him by the admirably practical manner in which he has described the different lesions and brought out their clinical significance. In fact, it would be difficult to understand how the work could be improved or be made more valuable to that large class of students and practitioners for which it is intended.

AN ELEMENTARY TREATISE ON HUMAN ANATOMY. By JOSEPH LEIDY, M.D., LL.D., Professor of Human and Comparative Anatomy and Zoology in the University of Pennsylvania, etc. Second edition. 8vo, pp. 933. Philadelphia: J. B. Lippincott Co. 1889.

THIS work, after having been published many years ago, comes to us in its second edition. It may be said, as it at present stands, to be anatomy simplified, and as far as possible, made interesting. The author has very successfully endeavored to make the study of anatomy comparatively easy by the presentation of an easy nomenclature and the avoidance of unnecessary names. The general plan is schematic and dwells largely upon principles, avoiding, as much as is consistent with scientific accuracy, the use of more than one common name for each organ.

Many of the illustrations are original, and present in a new aspect many an old picture of anatomical relations. It cannot be said that this book is anything more than it pretends to be, and yet it is everything that can be expected in a broad, elaborate, and comprehensive elementary anatomy.

HANDBOOK FOR THE HOSPITAL CORPS OF THE UNITED STATES ARMY AND STATE MILITARY FORCES. By CHARLES SMART, Major and Surgeon, United States Army. Approved by the Surgeon-General of the Army. New York: William Wood & Co. 1889.

THE title of this book gives to the civilian but a faint idea of its scope and utility. It treats not only of the post hospital and of the duties of the hospital authorities, but of active service in the field, of the elements of anatomy and physiology, of nursing, of the preparation of food, of first aid to the injured, minor surgery, management of cases of poisoning, disinfection, hospital and camp hygiene, etc. Indeed, it would be difficult to find any subject connected with the duties of an army surgeon or hospital steward which is not touched upon. Physicians and nurses in civil life will find the book as useful to them as it is to those for whose special benefit it was written. The illustrations are numerous and helpful.

IMMUNITY THROUGH LEUCOMAÏNES. By EUSEBIO GÜELL BACIGALUPI. Translated from the second French edition by R. F. Rafael, M.D. New York: J. H. Vail & Co. 1889.

THIS little work, as its title implies, is written in the effort to prove that the immunity against disease acquired through preventive inoculation is effected by means of leucomaïnes. By leucomaïnes the author understands the products of elimination which are the result of the vital functions of the specific micro-organisms. The immunity against any disease conferred by a previous attack is not due, he holds, to the fact that the organism has been deprived of substances necessary to the life of the microbe, but rather to the presence of the leucomaïnes which have been eliminated by the microbes during their previous visit. The author appears to assume that preventive inoculations in rabies, cholera, etc., are efficacious, and upon this assumption he bases in great part his argument. Consequently his theory appeals only to those who are already convinced of the value of these inoculations. The line of argument is well reasoned out, and the author's views are ingenious, if not wholly convincing.

COLLEGE BOTANY: INCLUDING ORGANOGRAPHY, VEGETABLE PHYSIOLOGY, AND VEGETABLE TAXONOMY. By EDSON S. BASTIN, A.M., F.R.M.S., Professor of Botany, Materia Medica, and Microscopy in the Chicago College of Pharmacy. 8vo, pp. 451. Chicago: G. P. Engelhard & Co. 1889.

THIS is a revised and enlarged edition of the well-known Elements of Botany of the author. He has succeeded very well in presenting his subject in an attractive and interesting way to the ordinary college student, a thing very much desired in these days. There is evidence throughout the work of a desire to teach the really practical points of the science, such as any student of pharmacy or materia medica may require as an introduction to more elaborate and technical researches. The illustrations are very many and very good. Altogether, the work will tend to popularize the study of a very interesting and useful science.

AMERICAN ARMAMENTARIUM CHIRURGICUM. 4to, pp. 846. New York: George Tiemann & Co.

CATALOGUES, as a rule, are not interesting, but this forms such a notable exception that it deserves particular mention. The publishers, so long known among the leading instrument makers of the country, have compiled a mine of information as to the almost countless number of instruments used in surgical operations, and have placed the profession under obligations for much that cannot be found in books, but still that should be known. No surgeon need now inquire for the name or uses of any surgical appliance within the range of his art, for here, in this formidably sized volume, with hundreds of beautiful illustrations and text descriptions, he has at hand everything he may need. It is an addendum to his works on surgery, and is quite indispensable as a book of reference whenever any new instrument or apparatus may be required for surgical work.

MALADIES DE LA LANGUE. Par le DR. HENRY T. BUTLIN, traduit de l'Anglais par le DR. DOUGLAS AIGRE, Ancien Interne des Hôpitaux de Paris. 8vo, pp. 424. Paris: Aux Bureaux du Progrès Médical. 1889.

THIS is an admirable translation of Butlin's work on Diseases of the Tongue, a notice of the original edition of which has already appeared in THE RECORD.

ŒUVRES COMPLÈTES de J. M. CHARCOT. MALADIES DES POUMONS ET DU SYSTÈME VASCULAIRE. Tome V. Aux Bureaux du Progrès Médical; E. Lecrosnier et Babé. Pp. 654. 1888.

THIS volume is a collection of the articles and lectures of Charcot upon diseases of the lungs, heart, and blood-vessels. Among the contributions are some that were delivered thirty years ago, and none are of more recent date than 1877. The volume has in a large measure, therefore, a personal and historical interest. But it also contains many clinical and pathological data of permanent value.

The work is ably edited by M. Bourneville, and it is illustrated with woodcuts and lithographic plates.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS. Consisting of Original Treatises and of Complete Reproductions in English of Books and Monographs Selected from the Latest Literature of Foreign Countries, with all illustrations, etc. Vols. I. and II. New York: William Wood & Co. 1889.

THE first volume of these monographs is completed with the March number. In a previous notice we referred to the nature of this publication, and to the contents of the first number. The two succeeding numbers answer fully the expectations created by the appearance of the first, and together they make a volume in which every practitioner may find something to interest and instruct him. The first number contains "The Pedigree of Disease," by Jonathan Hutchinson, F.R.S., a work which we have before noticed in these columns. The subject is one that is of the deepest interest to every medical man, and it is presented in a way that cannot fail to rivet the attention of the reader, and furnish him with much food for thought and earnest reflection. The second monograph is on some of the "Common Diseases of the Skin," by Robert M Simon, M.D., of London. It treats of the ordinary cutaneous affections which the general practitioner will be likely to meet in his daily practice, and is in every way a thoroughly practical and useful work. The number concludes with fourteen "Clinical Lectures on the Varieties and the Treatment of Bronchitis," by Dr. Ferrand, of Paris. The author has endeavored to classify the various forms of bronchitis, giving in detail the symptoms and distinguishing characteristics of each and their appropriate treatment. The second number contains an essay on "Gonorrhœal Infection in Women," by William Japp Sinclair, M.A., M.D., "A Critical Study of the Clinical Value of Albuminuria in Bright's Disease," by Dr. Pierre Jeanton, of Paris, and a monograph on "Giddiness," by Thomas Grainger Stewart, M.D., F.R.C.P.E., F.R.S.E. The last-named work is part of a series of lectures on important symptoms, in which the author defines the various symptoms, studies the different lesions of which they may be an indication, and traces the connection between the symptom and the underlying condition causing it. The last number of this volume contains five most valuable articles, two from the pen of Dr. H. von Ziemssen, the first on "Neurasthenia and its Treatment," the second on "Antipyresis and Antipyretic Methods of Treatment." The third article is an exhaustive treatise on "The Tongue as an Indication of Disease," by Dr. W. H. Dickinson. It is illustrated by woodcuts and colored plates showing the varying appearances of the tongue in health and in disease. "The Treatment of Cystic Goitre" is the subject of an essay by T. M. Hovell, F.R.C.S, and the concluding monograph of the series is a brief description of the new remedies introduced into medical practice during the past decade, by Dr. C. Cauquil, of Paris. This number also contains the title-page, table of contents, and index for the entire volume. This series of monographs is a new departure in medical literature, and is one that is deserving of success, for it puts in the hands of the general reader a mass of excellent material that would otherwise be beyond his reach. The editor has displayed good judgment in his selection of articles, for even in this first volume there is hardly a practitioner, be he a specialist or in general practice, but will find one or more subje ts of interest to him. The books are of a handy size, and the type, paper, and printing are so good that it becomes a pleasure to read the clear pages, apart from the interest aroused by the subject-matter of the different essays. Altogether, the subscriber to this series will find little cause to regret his expenditure, and much cause for congratulation in having acquired at so small an outlay so large an amount of instructive literature.

The second volume of this series of monographs is fully up to the first in point of interest and utility to the general practitioner. The first number of this volume, that for April, contains an essay on "Diabetes and its Connections with Heart Disease," by Jacques Mayer, M.D., of Carlsbad, and one on "Blenorrhœa of the Sexual Organs and its Complications," by Dr. Ernest Finger, of Vienna. The May number contains a paper by Sir Henry Thompson, on "The Preventive Treatment of Calculous Disease and the Use of Solvent Remedies," and an excellent article on "Sprains: their Consequences and Treatment," by C. W. Mansell Moullin, M.D., of London. The third number should be called a treatise rather than a monograph, for its entire four hundred and fifty pages are devoted to a translation of Dr. August Schreiber's recent work on "General Orthopedics, including Surgical Operations," the latest, and one of the best orthopedic works published in Germany. This bare enumeration of the titles of these monographs is sufficient to demonstrate the great value of the series, and we can only add that the physician who receives and reads these numbers as they appear, will find himself amply rewarded by his increased knowledge of the nature and therapy of disease obtained thereby.

LECTURES ON BRIGHT'S DISEASE. By ROBERT SAUNDBY, M.D. Edin.; Fellow of the Royal College of Physicians, London; Emeritus Senior President of the Royal Medical Society; Fellow of the Royal Medico-Chirurgical Society; Member of the Pathological Society of London; Physician to the General Hospital; Consulting Physician to the Eye Hospital; and Consulting Physician to the Hospital for Diseases of Women, Birmingham. With fifty illustrations. New York: E. B. Treat. 1889.

IN this little volume Dr. Saundby has presented us with a fairly exhaustive treatise on the subject of Bright's diseases of the kidneys, their pathology, symptoms, and treatment. The work is divided into three sections, the first being devoted to a consideration of general pathology, with chapters on albuminuria, the pathology of dropsy, of polyuria, and of uræmia, the pathological relations of tube-casts, the cardio-vascular changes, and the visual defects associated with renal disease. The second section deals with the clinical examination of the urine, and the third with the etiology, symptoms, prognosis, complications, and treatment of the different affections grouped under the name of Bright's disease. Throughout this section the reports of a number of illustrative cases are introduced in order to render more clear the author's explanations and descriptions. The illustrations in the book are noteworthy for their clearness, and most of them possess the merit of being original.

CLIMATOTERAPIA ESPAÑOLA EN LA TÍSIS PULMONAR. Por el DR. D. AGUSTÍN BASSOLS PRIM. Barcelona: D. Jaime Seix. 1889.

THIS is an interesting guide to the health-resorts of Spain, the Balearic and the Canary Islands, which have been found serviceable in the climatic treatment of pulmonary phthisis. It contains also much valuable information on the climatic treatment of this disease.

A Reference Handbook of the Medical Sciences: Embracing the Entire Range of Scientific and Practical Medicine and Allied Sciences. By Various Writers. Illustrated by Chromo-lithographs and Fine Wood Engravings. Edited by Albert H. Buck, M.D., New York City. Vol. VII. New York: William Wood & Co. 1889.

There is little to be said of this volume beyond what has already been said repeatedly of the volumes that have preceded it. The articles herein contained are those, in alphabetical order, from "Teratology" to "Worms," and each subject is treated in the concise yet complete manner with which those who possess the earlier volumes are already familiar. It is difficult, where there is so much that is excellent, to single out any one subject as especially worthy of mention. Yet we cannot refrain from commending with particular emphasis the articles on Tuberculosis. These include "Tubercular and Syphilitic Disease of the Kidney," by Morris Longstreth; "Tubercular Disease of Glands (Scrofula)," by F. Forchheimer; "Historical Sketch of Tuberculosis," by James F. Whittaker; "Pathology of Tuberculosis," by W. T. Councilman; and "Symptomatology and Treatment of Tuberculosis," by Hermann M. Biggs. "Phthisis Pulmonalis," by E. W. Schauffler, is found in a preceding volume. We venture to say that such a clear and satisfactory presentation of this subject, and one that is so fully up to date, is to be found nowhere else. But this subject is mentioned only because of the peculiar interest that it presents, and we are far from wishing to disparage by implication any of the other articles, which are, almost without exception, above criticism. One more volume will complete this invaluable work.

La Prostitution au Point de Vue de l'Hygiène et de l'Administration, en France et à l'Etranger. Par le Docteur L. Reuss. Paris: Librairie J. B. Baillière et Fils.

This is a work showing a great deal of painstaking research into a disagreeable subject. The facts and figures collected are most interesting, and cannot fail to be of great value to all students of social questions.

A Guide to the Practical Examination of Urine, for the Use of Physicians and Students. By James Tyson, M.D. Sixth edition. Revised and corrected, with a colored plate and wood engravings. Pp. 253. Philadelphia: P. Blakiston, Son & Co. 1888.

The appearance of a sixth edition of this little work attests its popularity and value. It ranks among the best of the numerous small manuals upon the subject of which it treats.

Dictionary of Volapük. By M. W. Wood, M.D., Captain and Assistant Surgeon, United States Army. Volapükatidel e Cif. New York: Charles E. Sprague, The Office Publishing Company; London: Trübner & Co. 1889.

The English-speaking students of Volapük, already quite numerous in this country, will welcome this excellent dictionary, the want of which has been greatly felt. The work is arranged on the plan of Bellows' English-French dictionary, the corresponding portions of the two vocabularies being placed on the same page. The vocabulary is very full, and will supply the needs of ordinary correspondence or essay-writing, but we confess to a disappointment in finding a great paucity of medical terms. It may be said that they would be out of place in a general dictionary, but as Volapük is intended for commercial and scientific uses chiefly, its vocabulary should contain the words suited to such purposes. However, it is necessary to have a stock of common words for use even in writing medical essays, and we doubt not that, if ever the medical world is ready to adopt Volapük as its official language, the present deficiency in medical and scientific terms will then be filled by a wealth of words amply sufficient to describe the most complicated of pathological processes. Anyone who has faith in the future of Volapük, and wishes to learn the language, will find Dr. Wood's dictionary indispensable, for, as we have said, with the exception of scientific terms, it is quite complete, and is so excellently arranged, and gotten up in so handy a form, that the thumbing of the book in search of words becomes almost a pleasure instead of a drudgery.

Recherches Cliniques et Thérapeutiques sur l'Epilepsie, l'Hystérie et l'Idiotie. Compte Rendu du Service des Epileptiques et des Enfants Idiots et Arriérés de Bicêtre pendant l'Année 1887. Par Bourneville, Médecin de Bicêtre, Sollier, Pilliet, Raoult, Internes du Service, et le Dr. Bricon. Vol. VIII., avec 27 figures dans le texte. Pp. 263. Paris: Publications du Progrès Médical; E. Lecrosnier et Babé. 1888.

These annual volumes always contain matter of much scientific interest, bearing especially upon the subjects of epilepsy and idiocy. The present work is no exception. Perhaps the most important contribution is one by Bourneville and Bricon on Procursive Epilepsy, in which this peculiar type of disease is elaborately studied.

The Operative Treatment of Hypertrophied Prostate. By Francis Sedgwick Watson, M.D., Surgeon to Out-patients, Boston City Hospital, etc. Pp. 167, 10x8. Boston: Cupples & Hurd. 1888. New York: J. H. Vail & Co.

The text of this work was read at the Congress of American Physicians and Surgeons, held in Washington last fall. It gives the history of the various remedial procedures which have been devised to relieve prostatic obstructions. It supplies a rational groundwork on which the greatly-increasing frequency of these operations may rest. A full supply of woodcuts of instruments, etc., is inserted, and thirty-four full-page photogravure illustrations are given with descriptive text. An epitome of the author's teaching is as follows: In prostatic obstruction, the radical operation is to be preferred, unless contra-indicated by the patient's exhaustion. Mercier's and Bottini's operations from the meatus are objectionable because applicable only to a limited number of cases, and they do not secure proper after-drainage from the bladder. This narrows the field to the perineal and supra-pubic methods. Anatomically, two-thirds of all cases likely to be encountered are operable through the perineum. Clinically, the perineal operations are the safest. "The inevitable conclusion" (says the author) "from these facts is, it seems to me, this: In a given case, open the membranous urethra, put in your finger, and explore. Twice out of three times the operation can be completed by this route. In the other third of the cases the long perineal distance, or the form of the median enlargement, will render the supra-pubic operation necessary. The work is a most excellent résumé of the subject, and the illustrations are of a high order. It is to be heartily commended.

Skin Diseases of Infancy and Early Life. By C. M Campbell, M.D., Edinburgh. Pp. 202, 6x4. London: Baillière, Tindall & Cox. 1889.

The author has endeavored to avoid alike the prolixity of a standard treatise and the bald incompleteness of a mere epitome. His efforts are welcome, as the honest narration of an extensive clinical experience always is, though it cannot be said that he has given us anything essentially new. It will be to the man commencing practice that the work will be especially valuable. The book possesses the value of being fully up to date, and can be safely recommended to students and recent graduates.

# Society Reports.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, March 27, 1889.*

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

THE special order of the evening was the presentation of specimens illustrating

LESIONS OF THE GASTRO-INTESTINAL CANAL.

DR. JOHN S. ELY presented a specimen showing

PIGMENTATION OF PEYER'S PATCHES,

supposed to be secondary to chronic congestion. Irregular, dark-brown streaks and spots of pigment gave a shaven-beard appearance to the Peyer's patches, and a few spots of pigment in other parts of the intestine seemed to be in the solitary lymph-nodules. The gut was from an Italian, about thirty-five years of age, who had pleurisy with effusion on the right side and broncho-pneumonia of the left lower lobe. Dr. Ely said that but little notice is taken in the books of this form of pigmentation, but that two situations for it are described—in the centres of the lymph-nodules and in the connective tissue around them. He thought, from the appearance, that the latter was the arrangement in the specimen presented.

Besides the pigmentation above referred to, there was

A DIVERTICULUM FROM THE ILEUM

about three feet above the ileo-cæcal valve, the usual site of Meckel's diverticulum. It was about three inches long and had the circumference of the small intestine. Dr. Ely said that the usual point of origin of these diverticula was opposite the mesenteric attachment, and that they ordinarily had no mesentery, but that the one presented originated from the side of the gut near the mesenteric attachment and was provided with a mesentery of its own. Its cavity freely communicated with that of the ileum. A blood-vessel of considerable size ran along the upper wall of the diverticulum nearly to its end, and it was suggested that this might be the remains of the omphalo-mesenteric vessels of the fœtus. That the diverticulum was lined with mucous membrane was shown by the presence of one of the pigmented Peyer's patches, half in the intestine and half in the diverticulum.

Dr. Ely also presented a specimen for Dr. Hodenpyl, which illustrated one of the conditions which may result from

PERSISTENCE OF THE OMPHALO-MESENTERIC CANAL,

of which Meckel's diverticulum is the remnant. The specimen was from a child, six months old, which since birth had had a small tumor, somewhat resembling a polypus in appearance, about three-fourths of an inch long, and an inch in circumference, protruding from the umbilicus. Dr. R. J. Hall, under whose care the patient was, discovered an opening in the centre of this tumor, through which a probe passed, apparently into the intestine. He ligated the mass at its base and excised it. The wound healed rapidly. Microscopical examination showed the tumor to be covered with mucous membrane closely resembling that of the small intestine, but infiltrated with small round-cells and broken down in parts. These changes were thought to be the result of exposure. The central canal, through which Dr. Hall had passed the probe prior to operation, was also found to be lined with mucous membrane similar to that covering the tumor externally. Immediately beneath each layer of mucous membrane the connective tissue and muscular layers of the intestinal wall belonging to it were to be seen, so that from without inward there was mucous membrane, submucosa, circular muscular fibres, longitudinal muscular fibres, subserosa, longitudinal muscular fibres, circular muscular fibres, submucosa, and mucous membrane again, lining the central canal. In other words, there had been complete prolapse of a portion of the persistent omphalo-mesenteric canal.

At the meeting of December 14, 1887, Dr. L. Emmet Holt presented a similar specimen to this Society, and afterward published the case in full, with a review of the literature, in THE MEDICAL RECORD (xxxiii., 1888, 431).

Dr. Ely presented several other specimens for Dr. Hodenpyl, illustrating

TUBERCULOSIS OF THE INTESTINE.

The first was interesting because the lesion in the intestine was confined to Peyer's patches, and resembled the lesion in the early stages of typhoid fever. A distinguishing feature was at once apparent, however, on inspecting the peritoneal surface of the gut, for in the immediate neighborhood of the Peyer's patches the lymphatics were distinctly outlined by miliary and submiliary tubercles scattered along their course. In one place it was thought that a miliary tubercle had blocked the lumen of the lymphatic and caused a damming back of its contents, since the vessel was uniformly dilated and filled with a milky liquid. These changes are well described by Orth.

A specimen of

TUBERCULAR PROCTITIS

was shown. It occurred in a patient not known to have tuberculosis, and had been diagnosticated carcinoma.

A third specimen illustrated

TUBERCULOSIS OF THE VERMIFORM APPENDIX,

which the speaker thought to be quite rare. The patients from whom these three specimens were obtained were all affected with chronic phthisis, and the lesions in the intestine were secondary.

DR. BIGGS said that he did not regard tuberculosis of the appendix vermiformis as of very infrequent occurrence, but, on the contrary, his experience led him to believe that it was quite common. He had often found it at autopsies, sometimes even when no tubercular lesions were to be encountered in other portions of the intestinal canal.

DR. T. MITCHELL PRUDDEN showed some

HAIR-BALLS FROM THE STOMACH OF A PIG.

The balls were made up of the hair of the pig, which had been licked off and swallowed, mixed with sand and other matters. The hair had a curious spiral arrangement showing the effect of the gastric movements. These hair-balls are found very commonly in the pig's stomach, but their occurrence is of interest by reason of the bearing that it has on human pathology, since they are sometimes found in the stomach of man.

Dr. Prudden then showed two

HAIR-BALLS FROM THE STOMACH OF A YOUNG WOMAN,

which had been removed by Dr. Finder, of Troy, and presented by him to the museum. There were two balls, one considerably larger than the other, which were made up of human hair, horse-hair, threads from blankets, pieces of string, etc. The girl had been insufficiently fed in her youth, and had got into the habit of swallowing many kinds of inert and indigestible substances.

Other specimens were presented of hair-balls from the cow's stomach, and also a number of concretions removed from the alimentary canal of an animal. These concretions were examples of

ENTEROLITHS,

which were formerly in great repute as drugs, being popularly considered as specifics in the treatment of nearly every disease to which man is liable.

DR. HERMANN M. BIGGS presented some specimens of

STRICTURE OF THE JEJUNUM,

associated with disease of the cæcum and vermiform appendix.

For about ten years prior to 1884 the patient, a man, forty-two years of age, had suffered from what he called attacks of wind colic. In March of that year the pains became localized in the right iliac region; an abscess formed, and was opened. The wound healed rapidly at first, but a small fistula remained through which air and fecal matters were passed. Three months later the external opening of this fistula was closed, as a result of treatment, but reopened after four years. During the greater part of this time, however, he was unable to take any solid food, on account of severe colicky pains which it caused, and was therefore confined almost entirely to a fluid diet. The amount of nourishment which he was able to secure in this way was insufficient to give him strength enough to permit him to work.

The patient was admitted to Bellevue Hospital in April, 1888, and was operated upon in June of the same year. On following up the fistula a large opening was found in the cæcum. The operation-wound healed readily, but the fistula did not close. In September Dr. Hartley operated again. The edges of the rent in the cæcum were freshened, and then united by two rows of sutures. The patient did well after the operation, but died in January of the present year from an attack of facial erysipelas and acute laryngitis.

At the autopsy an external opening was found in the right inguinal region, communicating by separate channels with the head of the cæcum and with the ileum. In the lower portion of the jejunum was a very tight stricture, barely admitting a small probe. The intestinal mucous membrane down to this point seemed to be perfectly normal. Below the seat of the stricture was found a small cicatrix, but it was longitudinal in direction and was not of sufficient size to cause any noticeable contraction. It was easy to understand, from the presence of this stricture, why the patient should have had wind colic. The vermiform appendix was apparently absent, and a large sinus was found extending from the cæcum just at the level of the ileo-cæcal valve. The valve itself was almost obliterated. There was a small opening, scarcely one-quarter of an inch in diameter, directly between the colon and small intestine.

A second specimen was presented of

INTERNAL STRANGULATION OF THE INTESTINE.

The patient was a young unmarried woman who gave no history of any previous illness. She had had a child four years before. A few days before her death she was seized with intense abdominal pain, nausea, and vomiting. The latter persisted in spite of treatment, and increased in severity. Cathartics failed to act, and the patient finally died. At the autopsy old peritoneal adhesions were found, and two or three small coils from about the middle of the cæcum had passed through an opening in these adhesions and had become strangulated. The condition, had it been diagnosed, might easily have been relieved by a laparotomy.

Dr. Biggs then presented a third specimen, illustrating a form of disease in which we sometimes have very few symptoms, viz.,

MALIGNANT DISEASE OF THE UPPER PART OF THE RECTUM.

The patient had complained of some trouble with the bowels, but had very little pain, and was not supposed to be suffering from any very serious disease. Suddenly very severe pain came on, and the patient died in a short time. At the autopsy a tumor was found in the upper portion of the rectum. Very deep ulcerations were present, and in two places the bowel was seen to be perforated. Both these perforations opened into the same ulcer, although they were separated the one from the other a distance of from one-half to three-quarters of an inch.

Dr. L. Emmet Holt presented a specimen of

PIGMENTATION OF THE INTESTINE.

It was removed from a child, three months old, who had died with marasmus without presenting any special clinical history. The pigmentation was very marked in Peyer's patches, in the colon, and in the mesenteric glands. There was no disease of the suprarenal bodies.

Dr. W. P. Northrup presented a gross specimen from a case of

ACUTE GASTRITIS AFTER THE ADMINISTRATION OF TURPETH MINERAL.

To a child, aged fourteen months, affected with diphtheria of the larynx and croup, was given an emetic of turpeth mineral (gr. iij.). This did not produce emesis, and one hour later ipecac was given and vomiting ensued. Three hours after the administration of the turpeth mineral the patient died. Cause of death, diphtheria of the larynx and broncho-pneumonia. The irritating emetic was not thought to have contributed to the fatal result, as the patient was in a dying condition when it was given.

This specimen and that of the following case were shown together to illustrate the irritant action of this mineral emetic.

On autopsy the stomach was empty, its walls in its cardiac half coated with thick, tenacious mucus, embracing small scattered masses of yellow sulphate of mercury, the mucous membrane beneath being intensely congested. The remaining portions of the stomach were normal, and the intestines were also normal.

The following was quoted from "The National Dispensatory of Stillé and Maisch," p. 786:

"*Turpeth mineral* is a powerful irritant, and, in sufficient doses, may act as a corrosive poison. . . . Several fatal cases are recorded. In a recent instance a healthy child, aged five months, died, poisoned by five grains of this preparation eleven hours after taking it. . . . Drs. Randolph and Roussel report the cases of five men, each of whom had at first five grains, and later three grains of the medicine. . . . The employment of so dangerous a remedy in a disease which involves no danger to life is inexcusable. The emetic action of this preparation is the first stage of its poisonous operation. The dose fitted to produce that effect is from two to three grains for a child. . . . It seems to be a superfluous article of the materia medica."

The same authors speak of its causing salivation.

Dr. Northrup then presented gross mounted specimens and microscope-sections from

A CASE OF ACUTE ULCERATIVE GASTRITIS AND NODULAR ENTERITIS, AFTER DIPHTHERIA OF THE LARYNX AND THE ADMINISTRATION OF TURPETH MINERAL.

To a male child, aged three and one-half years, suffering from diphtheria of the larynx and croup, was given an emetic of turpeth mineral (gr. iij.). No emesis was induced by it, and an hour later the dose was repeated. Two hours after the administration of the first dose vomiting ensued.

Twelve hours later the patient died. Cause of death, diphtheria and broncho-pneumonia. Before the urgent symptoms of croup set in the patient had been taking corrosive sublimate, gr. $\frac{1}{60}$, diluted in an ounce of water, every hour for twelve hours. The bichloride frequently reddens the mucous membrane of the stomach, and in diphtheria the solitary and agminate lymph-nodules of the small intestine are often enlarged moderately.

Dr. Northrup expressed the belief, however, that the excess of the lesion was due to the action of turpeth mineral.

On autopsy, in the cardiac half of the stomach, and more especially along the greater curvature, were found broad superficial ulcers, upon which was lying a thick coating of tenacious mucus and necrotic epithelium, with small scattered masses of turpeth mineral. The mucous membrane of the pyloric half and greater curvature was intensely congested, coated with mucus, with a few flakes of the mineral-emetic distributed through it.

Intestine: The lymph-nodules from pylorus to lower third of ileum—single and agminate—were exceedingly

enlarged. The mucous membrane was deeply congested in areas, coated with dirty brownish and greenish mucus, having here and there small masses of turpeth mineral surrounded with greenish mucus. Resting upon a Peyer's plaque, at the lowest part of the ileum affected, was a small mass of the emetic. The plaque was much congested and dusky and swollen. This point marked the limit of the congestion and excessive enlargement of the nodules and the presence of the mineral.

The remaining portion of the ileum and the colon were not congested; the lymph-nodules were slightly enlarged and the surface was thinly coated with mucus. In the colon was still castor-oil.

Case I. showed the effect of the presence of turpeth mineral in the stomach for three hours—localized severe inflammation.

Case II. shows the effects after twelve hours' presence—ulcerative gastritis—severe enteritis, with marked enlargement of the lymph-nodules as far as the mineral had advanced.

Microscope-examination of the seed-like bodies diffusely scattered through the small intestine of Cases I. and II. showed simple hyperplasia of the lymph-nodules.

Some other gross specimens and microscope-sections were presented, illustrating a case of

ENTERITIS WITH SWOLLEN PEYER'S PLAQUES AND ENLARGED FRANGIBLE SPLEEN.

A female child, five months old, wet-nursed, vomited two or three times two days before death—temperature, 99½° F. in the rectum. Her bowels moved freely after castor-oil. On the following day the patient went into collapse and died two hours later. No convulsions.

On autopsy was found marked swelling of Peyer's plaques and of a few solitary lymph-nodules of the small intestine, swelling (universal) of the mesenteric lymph-nodes, swelling and softening of the spleen. Heart, brain, stomach, and kidneys, normal. Colon nearly normal.

Dr. Prudden made cultures from the case for typhoid bacilli; none were found.

Microscope-examination of Peyer's plaques showed simple hyperplasia of lymph-nodules.

Dr. Northrup also presented gross specimens and microscope-sections from a case of

DIPHTHERIA OF THE PHARYNX AND ŒSOPHAGUS.

The interest of this case consisted in the particular location of the diphtheritic process in the pharynx and the extensive ulceration of the œsophagus.

One week before death the child, aged fourteen months, was affected with ulcerative stomatitis. Five days later a thin pellicle of pseudo-membrane was first discovered on tonsil. There was a suspicion that diphtheria was present before this time, but no membrane could be found. Diarrhœa the last two days of life.

On autopsy the tonsils were not swollen and no false membrane was found, excepting at the very lowest part of the pharynx, in the sinuses at the sides of the larynx called laryngo-pharyngeal. These corners were ulcerated, covered with rather thick slough, and on microscope-examination proved to be diphtheritic, having the usual characteristics, including numerous colonies of micrococci. There was then softening diphtheritic membrane in a position to drain directly into the beginning of the alimentary canal. The œsophagus, when opened, showed two straight rows of ulcers, circular, punched-out, having elevated walls, a little undermined, clean floor, varying in size from seven to three millimetres. These two rows were exactly opposed to each other before the œsophagus was slit open. The microscope-examination added only negative testimony, and the reasonable presumption was that the ulcers were of diphtheritic origin and that the necrotic tissue had sloughed away, leaving clean ulcers.

The stomach was covered throughout with a uniform grayish pellicle, not tenacious, this resting upon a congested mucous membrane. Microscopic examination showed catarrhal gastritis—no pseudo-membrane. There was also catarrhal entero-colitis.

A card specimen of a microscope-slide was then presented, showing

TUBERCULAR TISSUE FROM A JOINT

removed by operation. The specimen was of interest, showing unusually large and typical giant-cells, also the close grouping of typical tubercle granules with very little tissue between them—the whole arrangement being almost "schematic."

Dr. Holt, referring to the case of intestinal lesions found after the administration of turpeth mineral, said that he did not think the glands could have become so greatly enlarged in so short a space of time as had elapsed between the exhibition of the drug and the death of the child. Might not the lesions have been due to the action of the diphtheritic poison, independent of the presence of the mercurial?

Dr. Messenger said that he had used turpeth mineral a number of times in the early stages of laryngitis, and had never seen any but good effects from its employment. He had, however, never given more than one grain at a dose.

Dr. Roosevelt asked whether an analysis had been made of any of the unused portions of the drug which had not passed through the stomach and intestines, to ascertain if possibly there were not some of the bisulphide of mercury present. He did not think that the explanation of the production of the intestinal lesions, offered by Dr. Northrup, was entirely satisfactory; for, if the inflammation in both the stomach and the small intestine were caused by the turpeth mineral, why should it be most marked around the collections of the drug in one organ and be a diffuse inflammation in the other?

Dr. Prudden thought that it was a little hazardous to refer the production of the intestinal lesions wholly to the action of the turpeth mineral, since the diphtheritic poison was capable in itself of causing a swelling of the glands. Might not the lesions be due to the combined action of the poison of diphtheria and of the turpeth mineral?

Dr. Northrup said that he still saw no reason to doubt the correctness of his assumption. As far down the intestine as the lesions extended the presence of the turpeth mineral was found, but below this point, in the portions not yet reached by the poison, the intestine was normal. To his mind the relation of cause and effect seemed most evident, despite the objections raised by the several speakers discussing the case.

Dr. H. M. Biggs presented a specimen of

PERICARDITIS WITH EFFUSION IN A CHICKEN.

The amount of effusion was very great, and there was almost a perfect mould of the pericardium, made up apparently of fibrin and pus. There were also some small nodules on the surface, the nature of which he had not yet had time to ascertain, as the specimen had been received but a short time before and had not been carefully examined.

A second specimen was one of

ACUTE MILIARY TUBERCULOSIS.

The miliary tubercles were present in enormous numbers in the peritoneum, liver, lungs, and other organs. In searching for the source of infection the only old tubercular lesion to be found was in the articulation between the first and second pieces of the sternum. Here there was some cheesy matter containing tubercle bacilli. No other source of infection could be found anywhere in the body.

Dr. Sarah J. McNutt presented a specimen showing

INTRACRANIAL HEMORRHAGE

in a child eight and a half months old.

A male child, eight and a half months old, was admitted to the Babies' Hospital for gastro-intestinal catarrh and

congenital syphilis. Child died, March 26th, of inanition. There had been no history of convulsions or injury.

*Autopsy*, twenty-four hours after death, showed marked emaciation; there was evidence of a gastro-intestinal catarrh of long standing, œdema of the lungs was present, and the heart was distended by a dark clot. The liver, spleen, and kidney were apparently normal. The bones of the skull were thin, membranous in appearance, and could be readily cut by scissors. The anterior fontanelle measured three inches in its antero-posterior, and two inches in its transverse diameter. On cutting through this fontanelle two ounces of fluid, the color of weak coffee, escaped. The arachnoid membrane was seen to be thin, transparent, and raised by a clear, colorless fluid, in marked distinction from the rusty-colored fluid that had escaped on opening the skull. Lining the right frontal and parietal bones in their lower third, and also the adjacent skull-bones, was a thin, very vascular membrane, covering an area of two by three and a half inches, the vertical diameter being the shorter. This membrane, although adherent to the dura, was readily separated from it, leaving it pale and evidently free from hyperæmia. Beneath this membrane, at its centre, was a thin clot of blood about the size of a quarter of a dollar. No rupture of the blood-vessels of the pia could be found, nor any injury to the substance of the brain. The pathological condition would seem to have been caused by a hæmatoma of the dura mater, as in pachymeningitis hæmorrhagica.

Dr. Frank Grauer presented some specimens illustrating

ACUTE MILIARY TUBERCULOSIS,

removed from the body of a young man who had died in the Harlem Hospital. Up to four weeks before admission he had been apparently in perfect health. His chief complaint then was of severe pain, which was thought to be neuralgic. Upon admission his pulse was 68, temperature, 100.5° F., and there was slight rigidity of the muscles at the back of the neck. He soon became delirious. A diagnosis was made of meningitis. At the autopsy there was found to be acute miliary tuberculosis. The lungs were studded with tubercles, and tubercles were found also in the liver, spleen, and kidneys. The kidneys also contained small abscesses. The mesenteric glands were enlarged, tubercular ulcers were found in the intestine, and the brain also contained numerous tubercles.

A second specimen showed

ACUTE YELLOW ATROPHY OF THE LIVER.

At the time of admission to the hospital the patient was jaundiced and had œdema of the lower extremities. He was delirious, and remained in this condition until his death. At the autopsy hemorrhagic infarctions were found in both lungs. The heart was very pale, the aorta was atheromatous, and the coronary arteries were diseased. The peritoneum showed numerous points of hemorrhage, and there were also hemorrhages in the mesentery. The stomach and intestines were very much congested. There was meningitis, not very pronounced, and areas of hemorrhage were found in the brain. The liver was in a condition of acute yellow atrophy. Some fresh sections of the liver were examined under the microscope, but were not very characteristic of acute yellow atrophy. Other sections had also been made, but had not yet been examined.

The Society then went into executive session.

---

Deafness in Old Age.—Sapolini, of Milan, has described a method of his which he states he has successfully employed in sixty-two cases of deafness of old age. It consists in mopping the membrana tympani with a weak oleaginous solution of phosphorus. He claims that the treatment diminishes the opacity of the membrane, increases the circulation, and improves the hearing.—*Kansas City Medical Index.*

## OUR LONDON LETTER.

(From our Special Correspondent.)

THE PRESIDENCY OF THE COLLEGE OF SURGEONS—THE LOCAL GOVERNMENT BILL FOR SCOTLAND—THE NOTIFICATION OF INFECTIOUS DISEASES—SURGICAL TUBERCULOSIS AND PHTHISIS—THE REGISTRATION OF TRAINED NURSES—ENGLISH CONTRIBUTIONS TO THE PASTEUR INSTITUTE—THE MUZZLING OF DOGS.

London, July 21, 1889

Until the last few years the presidency of the College of Surgeons has—unlike that of the College of Physicians—been an annual office held in rotation by the senior member of the Council. Seniority on the Council came to be regarded as constituting a claim to the presidency. Such a system easily became possible under the mode of election to the presidency in force at the College of Surgeons, viz., by the Council selecting one of their own number to occupy the presidential chair. This method still continues, and is in marked contrast to that in vogue at the sister college, where the President is elected by the general body of Fellows. By the election of Mr. Savory to the presidency of the College of Surgeons, the old rule of seniority was broken through, and by his re-election for several successive years the tradition of looking upon the office as an annual one has been extinguished. Though a stanch opponent of democratic reforms in the College, Mr. Savory has been an able President, commanding respect even from his opponents. I need not refer to his eminence as a scientific surgeon. It is true that his continued re-election did not take place without comment, and it was rumored that Sir Joseph Lister's retirement from the Council was due to a feeling that he had been passed over by the repeated re-election of Mr. Savory as President. The latter has now declined further re-election, and the honor has therefore been conferred on Mr. Hutchinson, in whom the College has a worthy successor to Mr. Savory. Like Mr. Savory, Mr. Hutchinson is a Fellow of the Royal Society, and his name will be familiar to your readers as an able exponent of British surgery, and especially as an authority on syphilography, dermatology, and ophthalmology, in each of which departments, as well as in general surgery, he has left his mark in the domain of original research. Mr. Hutchinson is *facile princeps* in so many branches of surgery that he may be not unfairly described as a general specialist. Nor has he confined his attention strictly to surgical subjects, as witness his lectures on gout and rheumatism delivered before the College of Surgeons a few years ago. By his election as President the London Hospital is placed in the unique position of having upon its consulting staff the presidents of both the College of Surgeons and the College of Physicians (Sir Andrew Clark). It is curious to note that these gentlemen live next door to each other in Cavendish Square.

By accepting an amendment to the effect that every County Council in Scotland shall elect a medical officer of health, the Government has decidedly increased the value of the Local Government Bill for Scotland, now before the House of Commons. I refer, of course, to its value as a sanitary measure. The medical profession will, however, regard very differently the bill brought forward by the Government for the Notification of Infectious Diseases. It is proposed that such notification (to the medical officer of health for the district) shall be dual, viz., both by the head of the family or other person in charge of the patient, and by the medical man in attendance. The imposing the duty of notification on the medical attendant will be resisted by the medical Members of Parliament—it is to be hoped with success. Should the bill become law, a redeeming feature of it is that it is not to be compulsory, but only to apply to such districts as shall

voluntarily determine to adopt it. Where thus accepted, however, the above arrangement will be in force unless the bill should be amended in this respect.

In Mr. Howard Marsh's recent lectures on "Tuberculosis in some of its Surgical Aspects," delivered at the College of Surgeons, he remarked that one fact in connection with age demanded particular notice. That was that surgical tuberculosis and phthisis were prevalent at different periods, and were, speaking broadly, separated from each other by an interval of between five and fifteen years. It was remarkable that pulmonary phthisis and surgical tuberculosis very seldom occurred together, or as complications, the one of the other. At the Alexandra Hospital for Hip-disease, phthisis was very rarely met with, and he was informed by Dr. Douglas Powell that at the Brompton Consumption Hospital tubercular disease of the joints and caries of the spine were scarcely ever met with among the patients with tubercular phthisis.

The scheme propounded by the British Nurses Association, for the registration of nurses and for the formation of a Nurses' Register, on somewhat parallel lines to the Medical Register, is being strongly opposed. A "Memorial of Nurse-training School Authorities" has been drawn up, setting forth in brief some of the objections to the proposed scheme. It has already been influentially signed, among the signatures being those of representatives of most of the metropolitan hospitals at which nurses are trained.

The English fund in aid of the Pasteur Institute is slowly augmenting. Meanwhile dogs within the Metropolitan Police District are to be muzzled from August 1st until the end of this year.

## EXECUTION BY ELECTRICITY.

To the Editor of The Medical Record.

SIR: It is not my intention to enter into any controversy regarding the electrical resistance of man, for that subject has been ably investigated by several very competent observers, and the facts as stated by me can be verified by any one who will take the trouble to consult the original writings of Jolly or Gärtner, or the recently issued text-book of Lewandowski.

You appended a note, however, to my letter in your issue of July 27th, making a number of statements which I cannot allow to go unchallenged. I ask you, therefore, to print this second and final letter.

First: You state "the electrical experts who have referred to the enormous resistances of the human body refer to it as taken under peculiar conditions." This is incorrect. The resistances were determined by the use of large, well-moistened electrodes, made of brass and covered with sponge (Jolly); or of zinc electrodes covered with sponge and linen and dipped into a solution of zinc sulphate (Gärtner). In every instance the electrodes were accurately applied to the skin, with the aid of rubber bands or some other contrivance, and the tests were made on men and women of varying ages. The tests were made with the Wheatstone bridge. It seems to me, therefore, that such testimony is very much to the point.

Second: "With proper contact the human electrical resistance is not likely to exceed 2,500 ohms." This is a statement which has gone the rounds of text-books for years, but is absolutely disproved by the authors mentioned above. It is much nearer the truth to say that 2,500 ohms represent an unusually low human resistance; in fact it is near the minimum.

In therapeutic applications we can afford to wait until the electrical resistance has reached its minimum; in executions by electricity death should be instantaneous. This can be effected only in case the current is strong enough instantly to overcome the highest resistance. This resistance is as stated in my former letter. It is important also to keep in mind that the *current flowing through moist sponges is the chief agent in reducing resistance*, and not the moist sponges alone.

Third: The "expertness" of the testimony which intimates that the resistance is 500,000 ohms is called into question, since Mr. Edison has shown (*sic*) that the resistance of the human body, "with proper contact, ranges from 660 to 1,500 ohms." I am second to none in my admiration of Mr. Edison's genius, but he did not realize the conditions of the problem he attempted to solve, and he has simply determined (what medical men *erroneously* determined a decade ago) the *minimum resistance* of the human body, and not the maximum. I am a little surprised that any medical man should attach much importance to tests so hastily and so imperfectly made, and that he should prefer them to the careful investigations of medical men of the very highest repute. If man were a mass of metal Mr. Edison might be right; as it is, he is hopelessly wrong.

Fourth: Your statement that a current represented by the formula $CS = \frac{1}{2}\frac{5}{0}\frac{0}{0}\frac{0}{0}>$ passed through the brain instantly kills, requires some qualification. I am of the opinion that a current of one ampère may kill, but such a current will not pass through the body until the resistance shall have been reduced from 20,000 to 1,500 ohms, and there will be a very appreciable lapse of time before that figure is reached. It is a mistake to suppose that resistance is reduced instantly; different parts of the body vary in this respect. It has been shown that under strong currents the resistance of the feet, for instance, after the lapse of a minute, has been reduced only from 22,000 S units to 20,000 units (Jolly).

The differences between us may be summed up thus: You argue, let the executioner take his time, and when the minimum is reached the victim will be dead. No doubt; but what will the victim's sufferings be in the intervening minute or two? I say, the current should kill instantly, in spite of the maximum resistance of the criminal's body.

B. SACHS, M.D.

August 1, 1889.

[Our correspondent lays too much weight, we think, upon the exceptional statements of certain experimenters. The methods of testing human resistance are not difficult or complicated, and neither Jolly nor Gärtner can be credited with any superior and exclusive knowledge of the technique which would enable them to obtain more certain results than have experienced electricians like Edison. The intimation that human resistance under ordinary conditions of good contact is often 500,000 ohms is, we must repeat, somewhat startling, if not absurd. Every medical man who has dealt with human resistance knows very well that 2,000 ohms is a fair average with good contact. The formula referred to in point fourth was incorrectly printed, it should have been $CS = \frac{1}{2}\frac{5}{0}\frac{0}{0}$.—ED.]

## SOCIETY FEVER VERSUS YELLOW FEVER.

To the Editor of The Medical Record.

SIR: In THE MEDICAL RECORD for June 8th is an article entitled "The Cost of Yellow Fever Epidemics—The Epidemic at Decatur, Ala., in 1888," by W. E. Forest, M.D.

The paper is valuable and instructive, but there are two or three statements regarding the epidemic in Jacksonville Fla., which are decidedly at variance with the facts. Dr. Forest, of course, is not responsible for these errors, as he was not here and could only procure his information from unreliable sources.

He states that yellow fever reached Jacksonville as early as February; that it ran a mild course through the early spring and summer under the name of "society fever," but that its existence was concealed by the authorities, and that they did not admit its presence until August.

As one who treated a number of cases of this "society fever," and who practised through the epidemic of yellow fever and had the disease, I deny in the most positive manner that there was any similarity between the two

diseases. Those cases of fever that occurred in February and March were purely enteric or typhoid fever. The nickname of "society fever" was given to the disease in a foolish manner, because most of those attacked were among those who had been dissipating at hops, etc., during the season. It would be impossible for the veriest tyro in medicine to make a mistake in diagnosis between typhoid fever and yellow fever. It presented all the marked characteristics of enteric fever. The temperature ranged above normal from three to six or more weeks; the tongue was brown or black, and dry; the teeth covered with sordes; the passages from the bowels and bladder were frequently involuntary; there were delirium, subsultus tendinum and carphologia, and all the other well-known symptoms of typhoid. The fever in yellow fever lasts from one or two days to five days, and the patient is generally on the street in ten days. Not by the utmost stretch of imagination could this so-called "society fever" be considered as yellow fever. I am aware that Surgeon-General Hamilton has made the same statement as Dr. Forest, but he has had nothing upon which to base such a report, and it has also been corrected by local physicians. Another and most convincing proof that the two diseases were not the same is furnished by the fact that I know of more than a half-dozen cases of yellow fever (some in my own practice) which occurred among those who had had typhoid fever in the winter and spring, and three of these cases of yellow fever died. Was it ever before known that a person could have two attacks of yellow fever, and especially within a few months?

Dr. Forest states that there were only about ten thousand people remaining in the city, and that more than 10,000 cases of yellow fever were reported before the epidemic closed. We should be obliged to infer from this that a large number of people were not satisfied with having one attack, but, contrary to precedent, insisted upon having one or more additional attacks.

About one month after the fever broke out the Sanitary Association caused a census of the city to be taken. It disclosed the fact that there were then in the city 13,757 people, of which 9,812 were colored. The report of the Board of Health gives the total number of cases of fever as 4,696, divided as follows: Whites, 2,173; colored, 2,523. Deaths: whites, 331; colored, 99.

HENRY R. STOUT, M.D.

JACKSONVILLE, FLA.

## MISSOURI PHYSICIANS AND THE STATE BOARD OF HEALTH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will you kindly allow me to call your attention to some errors in your editorial, "Missouri Physicians and the State Board of Health" (THE RECORD, June 29, 1889). The State Board of Health is still in existence and doing as much work as the money at its disposal will allow. The Legislature made appropriations as follows: For Secretary's salary, $3,000; for expenses of Board for 1889–90, $1,000; to reimburse members of the Board for money spent in the discharge of duty, $1,070.60.

The State Medical Association appointed a committee of three physicians—Dr. E. A. Dourlan, St. Joseph; Dr. Pinckney French, Mexico, and Dr. Porter, St. Louis—to devise means for creating public sentiment among the laity in favor of the Board, and to also arouse the physicians to their duty. The session of the Legislature was almost at its close when the Association met, and before any action could be taken adjourned.

State Medicine in Missouri is laboring under considerable difficulty, and while it is true that the medical profession is partly to blame for the present condition of affairs, it is not true that they are altogether responsible.

I have taken the liberty of addressing you with regard to this matter, and trust that you will let your readers know the true condition of affairs with us.

Very truly, DANIEL MORTON, M.D.

## THE PHYSICIAN IN THE SUNDAY-SCHOOL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Allow me to make a statement prompted by reading your note in THE RECORD, July 20th, on "Going to Church." I have lived in this city for the past twenty-four years, and during that time (when at home) have seldom missed attending church once, and even twice, each Sabbath. Twenty-one years of the time I have been superintendent of a Sabbath-school, and have seen its numbers grow from one hundred and fifty to four hundred and fifty. I have seldom been absent from my school. I have never "hung around" my office on the Sabbath-day to catch business, but have always attended to necessary work. I have never reckoned the cost whether my church duties were a financial gain or loss. The duty was mine—the results belonged to God. "Trust in the Lord and do good; so shalt thou dwell in the land, and verily thou shalt be fed." I have been fed. Aside from duty, the change of mental work in these labors has proved to be a real rest and pleasure. If this little note should meet the eye of some young physician standing in the pathway of life where the lines diverge, allow me to say to you, earnestly, that you will secure better health, more genuine friends, and more real enjoyment by spending a spare hour each Sabbath in the Sunday-school, rather than on the base-ball ground. Life is short, and the "night cometh."

Respectfully yours,

G. W. H. KEMPER, M.D.

MUNCIE, IND., July 22, 1889.

## THE DANGERS OF BOTTLED MILK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: When we take into consideration milk as being one of the chief necessities of the sick-room and nursery, we cannot deny that *it*, above all things, demands our greatest attention. Oftentimes it has occurred to me, when seeing bottles of milk brought into the sick-room, how easily these may serve as a means of carrying poison or germs from one place to another. Realizing the danger and importance of this subject, I have given the matter some attention, and investigated the methods of several prominent milk-dealers of our city.

The first, and one important point to be considered in bottled milk, is the great amount of dishonesty practised among milk-dealers. It is very exceptional that the reality is as we picture it. There are very few firms who bottle their milk in the country. On the contrary, it is brought here about one or two o'clock in the morning (in large cans), and put in bottles after its arrival. Thus it may happen that your next-door neighbor may get the same milk for less money and of same quality for which you yourself pay extra. This is a great fraud, practised in our own city, and few suspect it. Like in every other business, the almighty dollar is the chief attraction. People have fancies, and those fancies must be gratified in order to retain their custom. The very thought of its being bottled in the country, retaining the fragrance and purity of the farm, is in itself sufficient to induce many people to buy it in this form. Yet it is fair here to state that some dealers are perfectly honest in this respect, while others are deceptive.

Again, when we think of these bottles being cleansed in a vat of water where dozens of others have been washed, how can we expect thorough cleanliness?

Many may say the large cans are no more thoroughly cleansed. But observation and common-sense convinces one that a large can could be much more thoroughly washed than a narrow-necked and small bottle. Admitting for a moment that the large cans were no better washed than a bottle, we could not contract half the poison, comparatively, from a forty-quart can as that could from forty one-quart bottles.

Here comes in the most important point in this paper,

viz., the contagion which might result from the indiscriminate use of these bottles. The very same bottles you use this morning may have been standing in a sick-room yesterday. Patients oftentimes drink immediately from the bottle. It is reasonable to suppose that, having stood in the sick-room, they are as much impregnated with poison as any article in the room. Often the bottles are closed in the sick-chamber, thus shutting in the dreaded germs and doubling thereby the extent of danger feared.

The ordinary cans from which milk is dipped never enter a house, and hence must be more pure. They stand no chance of being contaminated with disease. The only argument or point that can be raised in behalf of bottled milk is, that no dirt can enter, as occasionally does, in milk dipped from large cans. But who would not prefer a trace of dust to a trace of some dreaded disease.

The risk certainly is great, and should receive our earnest attention. E. BLACKWELL, M.D.

4 EAST THIRTY-SEVENTH STREET.

## PURE DRINKING-WATER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The question of obtaining pure drinking-water, either from our reservoirs in the cities or from wells and springs in the country, and preventing the contamination of the same, has been agitating the minds of the people for some time; and essays upon and discussion of the subject are filling the columns of the medical and lay press. In none of the recent publications, however, so far as I read them, have I seen any notice taken of an important observation made by Kraus, about two years ago, and published in the *German Archives for Hygiene*, 1887, pp. 237–252.

Kraus made a number of carefully conducted experiments on the behavior of various pathogenic and common saprophytic bacteria in drinking-water, and found that pathogenic bacteria of various kinds mixed with drinking-water from reservoirs or wells invariably disappeared from such water in a few days, having lost their ability of multiplying. Of Koch's vibrio, for instance, not a trace could be found after twenty-four hours. Typhoid bacilli cannot be demonstrated any more after six days, and those of anthrax after three. Now, both the bacilli of typhoid and Koch's vibriones are known to have retained their power of development in sterilized water for thirty-two and even eighty-two days, and it appears to be perfectly logical, therefore, when Kraus infers that the rapid destruction of the pathogenic germs in non-sterilized water is due to the action of the common water-bacteria. It is also interesting to know that the result of observation was the same, whether pure spring-water or impure well-water had been used in conducting the experiments.

What science has demonstrated here has been practically known to observing country people for many years. The farmers around Tannersville, for example, where I have been in the habit of spending my vacation for some years, have to keep a pretty sharp look-out nowadays to keep their wells and springs from poisoning by the more or less defective or badly located drains of the numerous boarding-houses and small hotels in and around the village and on their own premises. But they tell me that the infecting focus once discovered, and the ichorous oozing from it to the spring effectually cut off, the contaminated spring-water will run pure again in a week or two, and be fit once more for use without danger. I have not seen them, however, use the water of suspected wells in less than a month or two after cleansing them, and thought well of their precautions in that respect. On the strength of these significant researches of Kraus, to relax our vigilance as to the various contaminating sources of our water-supply would be folly indeed; but it is of great practical value to have it demonstrated that the common water-bacteria will make short work of pathogenic germs, and soon purify a polluted spring after we have succeeded in removing the cause of its pollution.

LEONARD WEBER, M.D.

# New Instruments.

## A NEW POCKET-CASE.[1]

BY HENRY S. STARK, A.B., M.D.,

NEW YORK.

MY experience in private practice has demonstrated to me that the busy practitioner of to-day cannot satisfactorily diagnosticate certain cases at his first visit to the bedside, although he possesses the requisite ability and the disease is sufficiently advanced for diagnostic purposes, for the simple reason that the clinical apparatus and appliances that are required for this purpose are too numerous and bulky to be carried in one's pocket, and that no portable method has heretofore been devised to obviate the difficulty.

In consequence, it frequently enough happens that the physician is only enabled to diagnosticate his patient's disease at a subsequent visit, when he comes armed with the necessary paraphernalia; in the meanwhile his treatment had been symptomatic, and the disease had been allowed to run its course, working its way for weal or woe.

Many of my readers will recognize the truth of this statement, and can recall cases *à propos* of my statements. That such a deficiency should have been tolerated in this advanced state of the medical sciences is indeed deplorable, and that no way out of the difficulty should have been devised is indeed a matter of surprise.

To illustrate my meaning, permit me to enumerate several cases that came within my own observation.

Several months ago I was summoned to the bedside of an apparently well-nourished man, about thirty-five years of age, who lay in a state of coma; his radial pulse was markedly weak and thready, pupils somewhat dilated and not responsive, breathing stertorous, temperature normal. The patient lodged with strangers who knew nothing of his previous history. Having satisfied myself that no accident had befallen my patient, I naturally thought of apoplexy, embolism, nephritic or diabetic coma. The absence of cardiac murmurs, and the equally dilated pupils, led me to exclude the first two; yet I was not in a position to state which of the latter two was the disease from which the patient was suffering.

It then occurred to me that if I had had with me the necessary apparatus for the detection of albumen, and the determination of the specific gravity of urine, I might have been able to properly diagnosticate the disease.

A second case presented the alternative of diagnosticating acute pleuritis or pneumonitis in an adult. The case was of such a nature that the aspirator-needle alone could have determined which disease was present; but not having a long aspirator-needle with me, and the hypodermatic needle proving, on trial, too small, the decision of this important step had to be postponed until the next visit.

A third case. I was requested by a colleague to administer ether to a patient prepared for operation. On looking at the patient, I asked the operator whether the patient's urine had been examined, as she looked "Brighty," and that the administration of ether might be likely to be followed by renal trouble. The operator acknowledged that this precaution had not been taken, and that the examination at this stage would be impossible, as neither of us had with him the requisite outfit for the gross examination of urine.

These cases will unquestionably serve to recall parallel cases in the daily practice of my readers, and will indicate the necessity of always having at hand, in our rounds from house to house, a certain outfit intended for clinical and diagnostic purposes.

A further inconvenience, occasionally encountered by the general practitioner, is the delay occasioned in having

[1] Read and demonstrated at a meeting of German Practitioners January 25, 1889.

a prescription prepared, especially in such cases where immediate medication is indicated.

We are summoned, I will say, in the dead of night to a severe case of hemorrhage, to a case of impending heart-failure, or of heart-collapse, or of poisoning; I venture to remark that the time consumed in writing a prescription, in waking the druggist and having him fill out our prescription, and waiting for the messenger with the medicine, has often proved disastrous to our patients.

To obviate the two difficulties indicated in my remarks, I have devised the pocket-case represented in the accompanying wood-cut.

The dimensions of the leather case, 5 × 2¾ × 1⅛ inches, make it easily portable in the coat, trousers, or even vest pocket.

The best conception of the case can be gotten by glancing at the drawing, which represents the case with the upper cover raised, exposing the contents to view. It is partitioned off into an upper and a lower compartment, each fitted with a sliding cover. At either extremity is a horizontal diaphragm with various-sized perforations, intended to hold the contents *in situ*.

The upper compartment contains (see Figure), enumerating from left to right, a complete hypodermatic outfit—barrel, two needles with wires, a vial for morphine; two thermometers with different-colored bulbs, the one intended for the rectum, the other for parts other than the rectum; a tongue-depressor, a pipette, a urinary test-tube with a urinometer, an aspirator with a three-inch needle, rendering it capable of use in all serous cavities. The barrels of the syringes are also variously colored to indicate their widely different purposes. The needle orifice of the hypodermatic syringe is enlarged to permit the ready entrance of a compressed tablet of some medicament intended for subcutaneous injections (see diagram), and readily soluble in water, which is afterward drawn into the barrel.

The lower compartment is analogous in construction to the upper, and contains compartments for five small vials for compressed tablets of such drugs as the physician selects, *e.g.*, ergotin, digitalin, cocaine, atropine, etc. There is also a place for red and blue litmus papers.

It will be seen that this "portable clinical pocket-case" affords the practitioner an opportunity of always having at hand a certain clinical and chemical outfit, which is called into constant requisition in a general practice.

270 East Seventh Street.

## Army News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 4, to August 10, 1889.*

Smith, Andrew K., Colonel and Surgeon, by direction of the Acting Secretary of War is granted leave of absence for seven days. Par. 12, S. O. 178, A. G. O., August 3, 1889.

Janeway, John H., Major and Surgeon, is hereby granted leave of absence for two months, with permission to apply for an extension of two months. Par. 3, S. O. 52, Headquarters Division of the Pacific, July 29, 1889.

Woodhull, Alfred A., Major and Surgeon, by direction of the Acting Secretary of War is granted leave of absence for two months, on account of sickness, with permission to leave the Division of the Missouri. Par. 5, S. O. 178, A. G. O., August 3, 1889.

Cochran, John J., Captain and Assistant Surgeon, now on duty at Fort Adams, R. I., by direction of the Secretary of War will report in person to the Commanding General, Department of the Platte, for temporary duty with troops *en route* to and at the summer camp at Fort Robinson, Neb. Upon the completion of this duty will return to his proper station. Par. 10, S. O. 180, A. G. O., August 6, 1889.

Gorgas, William C., Captain and Assistant Surgeon. By direction of the Secretary of War the leave of absence granted him in S. O. 84, July 3, 1889, Department of the Missouri, is extended two months. Par. 2, S. O. 182, A. G. O., Washington, August 8, 1889.

Banister, William B., First Lieutenant and Assistant Surgeon. By direction of the Acting Secretary of War relieved from further duty at Fort Wingate, N. M., and will report in person to the commanding officer at Fort Grant, Ariz., for duty at that station, relieving Captain Arthur H. Taylor. Par. 4, S. O. 178, A. G. O., August 3, 1889.

Taylor, Arthur H., Captain and Assistant Surgeon, upon being relieved at Fort Grant, Ariz., will proceed to Fort Wingate, N. M., and report in person to the commanding officer thereof for duty at that post. Par. 4, S. O. 178, A. G. O., August 3, 1889.

## Medical Items.

The Late Dr. I. O. Lea.—At the last meeting of the Richmond County Medical Society the following resolutions were adopted:

"*Whereas*, The announcement through the public journals of recent date has informally brought the sudden and untimely death of our late esteemed associate, Dr. Isaac O. Lea, to the attention of this Society; therefore,

"*Resolved*, That the Medical Society of the County of Richmond recognized in the late Dr. Lea one of its oldest, ablest, and most experienced members; a physician who, for the past thirty-four years, had held a position in the medical profession of this county second to none of his compeers. A genial, warm-hearted, and clear-headed man, who, when questions of vital interest to the profession were under discussion before this Society, never failed to take a prominent part in its deliberations, and a conservative position in regard to its action thereupon; a gentleman always in all his relations to his associates, and a physician whose place among us it will be difficult to fill. Peace to his memory.

"*Resolved*, That this Society tender its profound sympathy in their bereavement to the several members of our deceased associate's family, and that the Secretary be ordered to forward a copy of these resolutions, properly engrossed, to the son of deceased, as the family representative, and provide that the same be published in the county papers and in the New York Medical Record and New York *Medical Journal*.

"*Committee:* F. E. Martendale, *Chairman;* F. U. Johnston; J. Walter Wood; May R. Owen, *Secretary*."

Associated Movements of the Eyeball.—At a recent meeting of the Vienna Medical Society, Dr. Fuchs showed a child which was the subject of several congenital malformations, one of which was apparent absence of the left eye, the skin of the forehead being continued directly to the cheek, and no signs of eyelashes being present. Through the skin, however, a body could be felt, which was the eyeball. The movements of this eye followed exactly those of the normal eye, and as the associated movements could not have been learned, Dr. Fuchs insisted that they must be congenital.

### CHRONIC ENDARTERITIS AND ITS CLINICAL AND PATHOLOGICAL EFFECTS.[1]

(CHRONIC BRIGHT'S DISEASE.)

BY ARTHUR V. MEIGS, M.D.,

PHYSICIAN TO THE PENNSYLVANIA AND CHILDREN'S HOSPITALS, PHILADELPHIA, PA.

CHRONIC endarteritis is as much of a disease by itself—a separate entity—as are typhoid fever and measles. It is in the highest degree important that this fact should be recognized, and that the disease should be transferred from the position it now occupies among the obscure and little understood pathological curiosities, to the rank it is sure soon to claim for itself among the common and well-known complaints of every-day life. Until clinicians ordinarily are prepared to diagnosticate it during life and to announce it as a cause of death among their patients, its frequency of occurrence and importance will not be fully perceived. The name by which a disease is called is not an unimportant matter, for, if a name be accurately descriptive it is well received, and those who hear it easily comprehend what is meant, and thereby knowledge is rapidly diffused. The name "arterio-capillary fibrosis," proposed a good many years ago by Gull and Sutton, has never been commonly accepted, for the complaint cannot justly be called a fibrosis, and disease of the capillaries has never been proved to be an essential part of the process, and therefore, their description of the pathology was incorrect. The fact that our knowledge of the complaint is still most incomplete is no more reason for longer delaying to receive it among ordinarily recognized diseases than it would have been right for Bright to have withheld his great addition to the sum of pathological knowledge because there was still more to be learned in the same line of thought. Since there has come to me the feeling that I have more understanding of the pathology of the disease than formerly, the clinical management of cases often occasions a good deal of difficulty, by placing me in an awkward position with my patients when they or their friends ask: "What is the disease with which they are suffering?" To say Bright's disease in every case in which albumen and casts are found in the urine, would be very far from a correct expression of my understanding of the malady, for the instant conclusion of the public is that the patient has a disease which is as incurable as cancer, and one which will terminate in death almost as soon; whereas in many cases I *believe* that complete recovery, so far as the further progress of organic change is concerned, takes place, and I *know* that in many others the patients live in comfort for long periods of years. Such being the case, a name is needed by which to designate the disease, and it must be one from which the word kidney will be excluded; for it may be asserted that it is now known that the disease does not necessarily involve kidney change, and, if it does, that such change is only a very small part of the whole, and is subsidiary to something else. The pathological lesion which is always present, and which, so far as investigations made up to the present time show to be most widely diffused through the organs and tissues of the body, is an inflammatory thickening of the *intima* of the arteries and arterioles, and, whether the future will show this to be the primary and original change and the true cause or not, it is so widely diffused and so important that to call *it* the disease seems to me much more correct and descriptive than any other that has been proposed. Chronic endarteritis, a simple inflammation of the lining of the arteries, is the process by which the disease begins and thence extends to almost any degree throughout the arterial system, to some degree into the veins, and probably into the capillaries, as has been proved by the observations of others and my own.[1] This name should be modified to meet the needs of individual cases, as the pathological lesion attacks one or another or several organs, by saying—chronic pulmonary endarteritis, chronic cerebral endarteritis, chronic cardio-renal endarteritis, or other combinations as may be required to make the name accurately descriptive of the variations of one case from another.

To illustrate somewhat the clinical aspect of the subject, a few cases will be, as briefly as possible, given to show that the disease may be recognized during the life of the patient by physical and rational signs as well or better defined than are the diagnostic features of many well-known diseases. The cases will be grouped strictly according to their clinical features and the order of succession of symptoms, showing the disease to have taken possession of one or another or several important organs of the body:

CASE I.—A man about fifty years of age, after a year or two increasing very much in weight and becoming inactive, though previously very strong, was seized in the night with copious epistaxis, a thing he had not previously had for thirty years. Examination of the urine showed the presence of a trace of albumen and very numerous casts, and a month later he had cerebral hemorrhage of which he died in three days.

CASE II.—A man about sixty-seven years of age, who had always been typically strong and healthy, was taken with severe epistaxis several times within a day or two, a thing he had not had in fifty years. Physical examination of heart and lungs was negative, but there was some stiffening of the radial arteries. There were neither casts nor albumen in the urine, but slight œdema of the ankles was present. This observation was just made, and what shape the disease will take remains for the future to decide.

CASE III.—A woman about sixty-five years of age, very strong and well preserved, was seized with severe epistaxis; examination of the urine demonstrated the presence of albumen and casts. From this time she enjoyed quite good health, except that occasionally she would be vaguely out of sorts, when albumen and casts would be present in the urine, though at others absent, until she was seventy-seven years of age, when she had slight right facial paralysis, with partial aphasia and much distress and confusion of mind, of which she was perfectly conscious. The paralysis soon passed entirely away. After this there was gradually increasing loss of memory, though no perversion of mental function, and at seventy-nine years of age she was seized with sudden violent pain in the head, radiating down the back and into the limbs, particularly the lower ones; stupor came on, increasing to coma, and in a week she died.

CASE IV.—A woman about fifty-nine years of age, who had always been unusually strong, except that she was sub-

[1] THE MEDICAL RECORD, July 7, 1888, and Transactions of the College of Physicians, Philadelphia, vol. x., 1888.

ject to take cold and have quite violent cough, was seized with epistaxis which recurred several times within a week or two. Examination of the urine revealed the presence of a trace of albumen, and after careful search by two observers, one of them found one or two casts. Physical examination was negative, the lung and heart sounds being natural, though when she had cold and cough, bronchial râles would be present. From that time to the present she has been very nervous, complaining of many vague sensations, and having become visibly much older. She cannot walk freely and with comfort, as her steps are always short and uncertain and she tires easily. Now, two years later, there is a distinct and rather harsh aortic murmur which is systolic in time, and this, though she has never had any acute illness in the two years that have elapsed. A trace of albumen is constantly present in the urine, and occasionally a few casts.

CASE V.—A man of about sixty years of age, in the hospital ward, suffering with typical chronic Bright's disease—dropsy, albumen and casts in the urine, hydrothorax, and great hypertrophy of the heart—declared upon most careful cross-examination that the first deviation from health with which he had suffered was a disposition to take cold readily and have violent cough, and this for some time before any of the other conditions mentioned came upon him.

CASE VI.—A man about sixty-six years of age, was for a year or two subject to violent spasmodic cough with much expectoration; he had bronchitis and some enlargement of the heart, and œdema of the ankles, but neither albumen nor casts in the urine; five years later he is still living, but there has been in that time no opportunity to see or examine him.

CASE VII.—A man fifty-six years of age, previously healthy, except that he had at times passed gravel, had bronchitis and coryza with more oppression than the physical signs seemed to account for. Examination of the urine revealed the presence of albumen and casts. For four years subsequently albumen and casts were found from time to time upon examination, but since that period there has been no opportunity to test the urine. With the exception of much rheumatic stiffness and a tendency to take cold readily, he is still living and healthy at seventy-one years of age.

CASE VIII.—A man previously very healthy, had, when about sixty years of age, an attack of pneumonia of subacute character. Since that time he has never been the same, having lost his activity and strength, and now, at sixty-seven years of age, his condition is as follows: He has lost a good deal of weight; some of the arteries are rigid; he is very easily fatigued, and complains that his legs are almost paralyzed, so great an effort is it to him to walk, though to all appearances his gait is natural enough, except that it is rather shuffling. The heart-action is rapid and feeble. Neither albumen nor casts have been found in the urine.

CASE IX.—A woman, about sixty-five years of age, complained of not being well, though she was not confined to bed. Physical examination revealed dulness over one lung posteriorly and very harsh bronchial respiration, but no moist sounds or râles of any sort, and no expectoration —plainly a case of pneumonia. There was a slight mitral valve murmur, and the urine contained albumen and casts. This condition of affairs continued, and she gradually failed, though at no time having any urgent or alarming symptoms, and after four months died very quietly.

CASE X.—A lawyer, fifty-four years of age, in full practice, had an attack of acute catarrhal pneumonia. He was ill for several months, and during the whole time there were albumen and casts in the urine, and for between two and three years afterward. After that they disappeared, and eight years subsequent to the attack the urine was found to be healthy; since then there has been no opportunity to examine it, but the patient is still living, appearing to be healthy, and practising his profession at sixty-eight years of age.

CASE XI.—A man about sixty-six or -seven years of age, who had always been well, for a few months did not seem quite like himself in strength, and finally had some cough. Examination revealed the presence of subacute pneumonia, and albumen and casts in the urine, though there were not then nor subsequently any symptoms which could be attributed to faulty renal action. There was extreme atheroma, so much so that one radial pulse was almost extinguished and the vessel very hard. After a few weeks the lungs cleared and he got about again, though continuing very weak. In about three months there was a return of the pulmonary trouble, with cough and expectoration, and the breathing was quite rapid, though he declared he had no pain, or even oppression. In a few weeks he died, fading out very quietly, without violent or urgent symptoms of any kind.

CASE XII.—A man who is now about eighty-four years of age, and, for his age, quite active, has for the past fifteen years had very frequently albumen and casts in his urine, and during most of that time his breathing has been somewhat wheezing, with bronchial and asthmatic râles to be heard in the chest.

CASE XIII.—A man, who inherited gout, was, for ten or twelve years, subject to the arthritic form. When between fifty-seven and fifty-eight years of age he began to

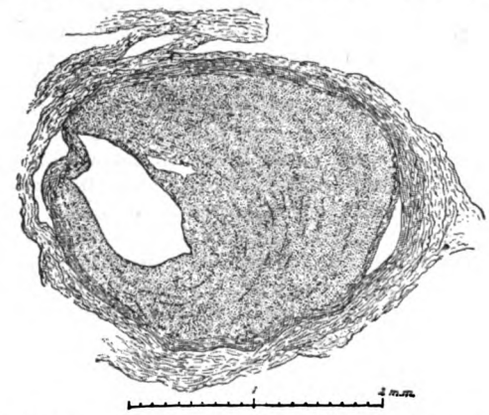

FIG. 1 (× 17 diameters) represents the large branch of the left coronary artery of the heart, which descends in the interventricular septum. The calibre of the vessel is almost closed by overgrowth of the intima, the opening which remains being represented toward the left in the picture. The other spaces were either the result of tearing in mounting, or were filled with some material which did not stain and was transparent. The muscular coat is represented by lines, and the adventitia by lighter ones outside; all the material inside these, represented by dots, is the proliferated intima. The part of the vessel represented here contained no calcareous material, though elsewhere there was abundant mineral deposit.

have some shortness of breath, and six months later had one night an attack of oppression so violent that it was thought he would die. Albumen and casts were found in

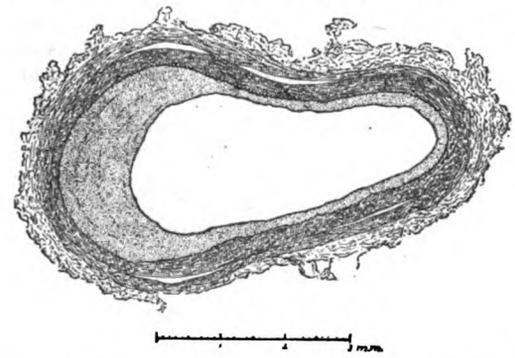

FIG. 2 (× 9 diameters) represents one of the first branches of the renal artery as it entered the hilus of the kidney. The great and irregular thickening of the intima is very marked, and the plicated membrane is distinctly visible around the greater part of the circuit forming the boundary between the intima and muscular coat.

the urine, and from this time he failed, and died at sixty years of age, having spent the last eight months of his life in the house in most shocking suffering from general dropsy and great oppression, and latterly quite insane (not delirious), being very suspicious and having marked delusions. The heart was greatly hypertrophied and the

arteries diseased (see Figs. 1 and 2), and once he had a slight uræmic convulsion.

CASE XIV.—A woman about sixty years of age had, for a good many months, been getting less and less able to walk. Examination revealed the presence of albumen and casts in the urine, stiffening of the mitral valve, and a tumor in the right hypochondrium, which was thought to be due to gall-stones in the bladder; this, however, she had had for a good many years, and it seemed quite latent so far as giving rise to any irritation was concerned. Many of the arteries were stiff. She walked very feebly and with a shuffling gait, hardly lifting the feet at all, though there was no true paralysis. The feebleness in walking increased, and the legs wasted until the calves could almost be spanned with the thumb and forefinger, and it was with difficulty that she could even cross a room. One day she fell upon the floor, simply losing her balance, and broke the neck of one femur, and never was able to walk again. After this, and before too, her intellectual powers became less and less, she lost memory to a great degree, and at last became mildly insane, having delusions. She failed gradually, and after two years died, without having had any violent or active symptoms beyond those mentioned, except that for some time before death there was marked general hyperæsthesia.

CASE XV.—A woman about sixty-two or -three years of age has, during the past six years, been subject to attacks of sharp fever which prostrate her very much and keep her from one or two days to a week in bed. At these times albumen and casts have very frequently been found in the urine. She has the signs of slight mitral valve stiffening. Except when suffering with an acute attack, she lives a very active life, doing a great deal of charitable work. During the last eight months she suffers with most persistent prickling sensations (pins and needles) in the hands and feet, and becomes easily fatigued, complaining that her legs are often so heavy that she can hardly lift or drag them along.

CASE XVI.—A man thirty-two years of age had, a little more than two years before his death, an attack of acute rheumatism, after which he had always shortness of

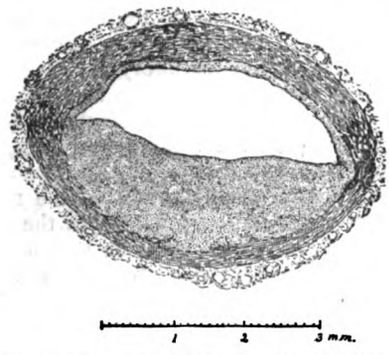

FIG. 3 (× 10 diameters) represents also the branch of the left coronary artery of the heart which descends in the interventricular septum. The enormous and irregular thickening of the intima is very evident; the plicated membrane is distinctly visible around half the circuit upon the side of least thickening; upon the same side also the muscular coat is nearly twice as thick as upon the other. There are two explanations for this irregularity of thickness of the muscular coat, the one, that it is hypertrophied upon the side on which it is thickest, the other, that upon the opposite side it has been partially destroyed by the invasion of disease.

breath and palpitation on exertion. During the last seven weeks of his life he had all the commonly accepted signs of Bright's disease—dropsy, albumen and casts in the urine, frequent micturition, cough with bloody expectoration, enormous hypertrophy of the heart with aortic regurgitation, great oppression and difficulty in breathing, violent vomiting, and pain in the belly. He died in great suffering. (See Fig. 3.)

CASE XVII.—A man who during all his life had been very strong, was taken at about sixty-three years of age with attacks of vertigo. Examination showed that his heart acted with the most extreme irregularity, but that there was no sign of valvular disease, and the urine contained neither albumen nor casts. These symptoms continued for about one year, but during the last year, he being now about sixty-five, the condition is much improved, as he seldom has any vertigo and the heart is no longer very irregular, though occasionally intermittent in its action. There is some stiffening of the arteries.

CASE XVIII.—An infant that was deserted by her mother when between two and three weeks of age, having already before this time lost weight and failed in general appearance and condition instead of gaining, was placed in an institution. The urine was never examined. In spite of all that could be done for her she soon presented the appearance of marasmus in a most typical manner, and at last, after having for a good while looked like an old, dried-up woman, she died at five months of age. (See Fig. 4.)

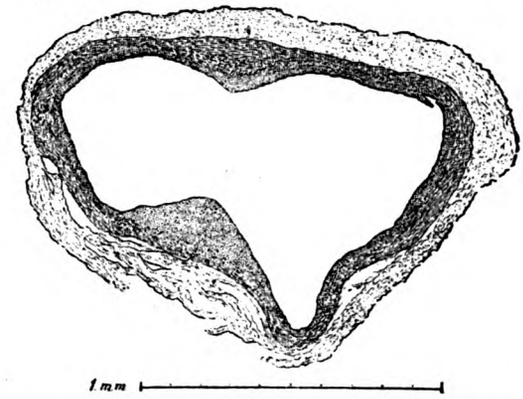

FIG. 4 (× 40 diameters). The infant was aged five months. This is the left coronary artery of the heart just after its origin in the aorta, from Case XVIII. The irregularity of thickening is very evident, and it seems equally positive that the process of disease belongs to the lining of the vessel, for the muscular coat is distinctly visible outside of the area of disease, and does not appear to be very much altered, except that in some places the process seems to have invaded it, as well as having produced masses inside the vessel. The plicated membrane is represented by two fine lines with a white space between them, and is visible around the entire circuit, except in the thickening which is represented in the lower part of the picture, where the process of disease has involved the muscular layers to a great extent.

These cases were selected because they presented, in a typical manner, the clinical symptoms it has been my desire to group together, so that anyone who will study the subject can readily and with precision make a diagnosis of the disease. In Cases XIII., XVI., and XVIII. autopsies were made, and the arteries figured in the plates were taken from them. I could have given a larger number in which autopsies were made and the lesion found, and such specimens are still in my possession, but the three only were introduced because they are fair types of the lesion, and the introduction of more would have made this paper too long, especially as my desire has been to deal now more with the diagnostic and prognostic features of the disease, and to touch upon the pathology, with which I have dealt more at length elsewhere,[1] only so much as was necessary to make plain my meaning, without going so deeply into pathological technicalities as to fatigue the ordinary practitioner. Only three of the cases (V., XVI., and XVIII.) were hospital patients, the rest being taken from the records of private practice, and were selected because they were under observation, in almost every instance, for long periods.

Cases I., III., VII., X., and XII., have already been alluded to in a paper which appeared in the "Transactions of the College of Physicians of Philadelphia," vol. vi., 1882, entitled "Clinical Observations on Albuminuria, Based upon a Study of Sixty-two Cases Seen in Private Practice."

One of the cases (XVIII.) may be thought to have been improperly placed in the group, as it was one of ordinary infantile wasting, or, if the name be not objectionable, marasmus, and it presented no unusual clinical features or symptoms; but it has so long seemed to me that there must be some parallelism between the disease under consideration in adults and some of the cases of infantile

[1] Transactions of the College of Physicians, Philadelphia, vol. x., 1888, and MEDICAL RECORD, July 7, 1888.

wasting, that, upon finding the pathological lesion so typically developed (see Fig. 4), I added the case to the group; where from the pathological standpoint certainly it justly belongs. Infants dying in this way grow to look so exactly like those who die of old age, that everyone who has written upon the subject has remarked upon the similarity of the appearances presented, though the two modes of death are the antipodes of human existence. Upon previous occasions I have published three papers on this subject, and it will be my endeavor not to unnecessarily repeat what will be found in them. They are as follows: "Clinical Observations on Albuminuria, Based upon a Study of Sixty-two Cases Seen in Private Practice," "Transactions of the College of Physicians, Philadelphia," vol. vi., 1882; "Cardiac Degenerations and Bright's Disease the Result of Changes in the Intima of the Arteries and Veins," *American Journal of the Medical Sciences*, June, 1888, and "A Study of the Arteries and Veins in Bright's Disease," "Transactions of the College of Physicians, Philadelphia," vol. x., 1888, and the MEDICAL RECORD, July 7, 1888.

*Symptoms and Diagnosis.*—The symptoms of this disease are of such a nature as, in marked cases at least, to make the diagnosis an easy matter. Perhaps these symptoms cannot be better elucidated than by passing them in review and trying to collect them together in such groups as they would seem most naturally to fall into, for to my mind certainly they present a clinical picture which is most striking and characteristic. Hemorrhage, whether it appear in the form of epistaxis or of cerebral apoplexy, is a marked symptom, and one which should always rouse the physician to investigate whether endarteritis has not taken possession of some part of the vascular system of the patient. Epistaxis was the earliest symptom in the first four cases narrated to draw attention to any deviation from health in the patients. Any externally distinguishable stiffening of the arteries, commonly called atheroma, is to my mind positive evidence of the presence of endarteritis, for I have yet to examine an atheromatous artery exhibiting diseased middle and external coats and a healthy intima. Many of the commonly received symptoms of kidney disease, though they do most certainly indicate that that organ has undergone grave pathological change, causing damage to a greater or less degree, and which will be permanent and irreparable, show much more, if the warning is but heeded, that extensive and often much more dangerous degenerations are taking place in other and perhaps far-away organs and tissues of the body. Occasionally, in patients affected in this way, there may be from time to time attacks of fever, and at such times albumen and casts may be found in the urine, as in Case XV.

The various manifestations of disturbance of cardiac function are among the most constant accompaniments of endarteritis in any form, and as far as present knowledge leads us to a comprehension of the subject, among the most important and of greatest gravity. It has long seemed to me the merest folly, in all cases of demonstrable cardiac valvular disease, to set it down as caused by rheumatism or chorea, or even to over-exertion of the body, as is so commonly done by clinicians; or, on the other hand, to believe that rheumatism commonly induces endocarditis and stops at that. Cases IV. and XVI. are types of what may happen in these respects, and as they afford positive evidence of what sometimes does take place, they are of more value than many negative cases, for it is an axiom in logic that it is hard to prove a negative. In Case IV. the patient had no cardiac valvular disease two years ago, now she has positive evidence of aortic stiffening, and yet during that time she has never had any acute attack of illness, but has most positive signs of endarterial inflammation—stiffening of the superficial arteries, albumen and casts in the urine, the valvular heart disease, great nervousness, with loss of muscular power, and general rapid aging in every respect—all coming on after a violent series of attacks of epistaxis which ushered in the loss of health. Most certainly the valve change was not due to rheumatism, or chorea, or over-exertion of the body in this case, for no one of these possible causes has obtained, and if it be not granted that the inflammation that certainly has existed in the lining of the arteries has crept slowly and silently into the heart, there to accomplish the same fell work that it has undoubtedly done in the vessels, no other more reasonable explanation, at any rate, can be offered. The history in Case XVI. seems equally positively to show that the effects of rheumatism by no means stop after having injured the endocardium and valves, for in that case, from the time of the acute attack, the patient was no longer well, and in about two years died of Bright's disease, with a typical development of the symptoms and pathological lesions (see Fig. 3). Looking at the case from my own standpoint, I feel quite satisfied that the man had rheumatic endocarditis, and at the same time or soon after, and as a continuation of the same process of disease, endarteritis, at first acute and then continuing in a chronic form after he seemed well, and that by this avenue and in this way almost all his organs became gradually involved. It would be easy to accept the old mode of explanation—rheumatic endocarditis, aortic regurgitation, cardiac hypertrophy, increased arterial tension, hypertrophy of the muscular coat of the arterioles, venous congestion of the kidneys, and thus Bright's disease secondary to the rheumatic heart disease. This, as an explanation, has long seemed to me more than merely theoretical—it is positively fanciful and visionary, and besides, it totally fails to explain many of the most evident and important of the pathological lesions. For the sake of argument, suppose we accept the hypothesis as affording an adequate explanation of the lesions so far as the heart and kidneys are concerned—how are the diseased conditions of the other organs to be explained? The lungs were much infiltrated with cellular overgrowth and their vessels were markedly thickened, especially the intima, the liver in a state of granular disorganization, the blood-vessels of the spleen very thick, and the aorta (though the man was only thirty-two years of age) very atheromatous, besides which the heart exhibited fibroid degeneration, and its arteries were in the last stages of degeneration, not hypertrophy (see Fig. 3). As an explanation for all this, is it not more easy to believe, and more consonant, too, with our knowledge of the migratory habits of inflammation, that an endarteritis, rheumatic in origin, acute at first, and then continuing as a chronic process, took possession of the lining of the arteries, and creeping from place to place by avenues so widely open as actually to invite invasion, thus gradually produced the result, than to distract our brains by trying to follow the intricacies of the older explanation, which is so complicated that from the time it was originally proposed it has always been looked upon with suspicion?

Œdema coming on without discoverable organic lesion sufficient to account for its presence, is often an indication of the existence of endarteritis (Case II.), and the same may be said of vertigo and irregular heart-action in some instances (Case XVII.).

The fact that symptoms connected with pulmonary disorder or actual lung diseases are often the earliest departures from health in those who afterward die of what has been called chronic Bright's disease, was one of the things which first caused me to feel any doubt of the sufficiency of that mode of explanation of the train of symptoms. Among the cases detailed this is plainly illustrated, for in eight at least, Cases V. to XII., inclusive, the mode of origin was an attack of pulmonary disease, and six of them certainly were cases that everyone would agree to call Bright's disease. This phase of the complaint may declare itself in the form of an attack of bronchitis, either by cough and expectoration without physical signs; or with a full development of bronchial rales, as the case may be; or catarrhal pneumonia, a disease which is capable of taking upon itself very many and varying aspects; or of asthma or emphysema; or, lastly,

there may be one of the forms of oppression, either sudden and violent, or coming on gradually and being very persistent, which are such common and well-known accompaniments of chronic disease of the kidney. These manifestations of pulmonary disorder may be acute and accompanied by great fever and general disturbance of the system, of such a character as to constitute an acute illness confining the patient to bed; or their onset may be so insidious as to attract little or no attention until a physician discovers that his patient is going about with a lung half solid from pneumonia (Cases IX. and XI.).

Functional disturbance of the liver is not uncommon, and the frequency with which the blood-vessels are thickened shows it to be likely that it has here, too, some causative relation. The spleen is incapable of inducing clinical symptoms of which at the present time we have knowledge, but it is one of the organs in which the pathological change of the vessels is most commonly found.

Symptoms manifesting a disordered state of the nervous system have long been well recognized as a common consequence of this disease, and of late several interesting and valuable communications upon the subject have appeared in different medical journals;[1] but the earliest attempt probably to arrive at a scientific understanding of their cause was made in the paper of Gull and Sutton.[2] In these symptoms of disordered nervous function do we find what affords perhaps the strongest confirmatory evidence that the disease has its origin in the vascular system, and at the same time the best proof that the old theory of origin is totally untenable. There has never even been an attempt made to explain the cerebral apoplexy and many other less formidable symptoms of nervous disorder that are so common, and clinically so fully recognized, except in a general way to allude to the many things that increased arterial tension is capable of effecting. The most common of these symptoms—as has already been somewhat brought out in the detail of cases given—are: cerebral apoplexy, general muscular weakness, with shuffling gait but without actual paralysis, and, in some instances, wasting of the muscles; change of temper and disposition, nervousness and decline of mental power, especially loss of memory, and even mild insanity; and in old people in the latter stages of the disease, most commonly after they have got so weak as to be confined to bed, a curious general hyperæsthesia which does not seem to be confined to the skin, for there is great pain caused by any movement.

Rheumatism and gout seem to be near relatives of endarteritis, or at least closely bound up with it. In one of the cases (Case XVI.) rheumatism, and in another (Case XIII.) gout, seemed to set fire to the train that finally led to the fatal result, and in both, as has already been alluded to, post-mortem examinations were made, and the lesions of chronic endarteritis in a typical state of development found (see Figs. 1, 2, and 3), and they both died with all the ordinarily recognized symptoms of chronic Bright's disease.

*Prognosis.*—In the clinical management of cases there is nothing which occasions more difficulty than the question of prognosis; for, to anyone who has had to deal much with the disease, one thing at any rate is very plain, that many cases that a few years ago would have been looked on as necessarily fatal, recover entirely, and others regain sufficient health to live for many years in comfort. It is wonderful how differently two cases, that at the outset seemed very closely parallel, may terminate, the one perhaps living for many years, and the other dying within a few months; this is exemplified in Cases XI. and XII. It does not seem possible to doubt that in Case X., for instance, entire recovery has taken place, though as albumen and casts were present in the urine, and the patient was in ill-health for more than two years, he certainly had chronic Bright's disease; and Case VII. is one in which, even if it cannot be positively asserted that complete recovery has occurred, at any rate there has been such a physical condition that for fourteen years the man has had a very enjoyable life. It seems possible to explain this, so far as the kidney is concerned, only by the belief that there was, at the time of the acute attack, a wedge-shaped spot or spots of inflammation with round-cell infiltration, the broad base of the wedge being toward the cortex, such as are so commonly seen in sections cut from the organs of persons dying in this stage of the disease, and that this has in the course of time healed, after having destroyed a greater or less number of tubules, and left in their place a small scar. Why it should so long have been supposed that the kidney was incapable of getting over the effects of an inflammatory process which is in no wise different from what occurs elsewhere, when it is perfectly well known that every other organ and tissue in the body can undergo regeneration to a greater or less degree, is a thing which is incomprehensible! In view of these facts we should, as physicians, be very slow to give a fatal prognosis, except in cases in which the morbid changes have progressed so far as to make our ground very certain. There is no combination so bad, and none which so fully seems to justify a very gloomy prognosis, as the presence of albumen and casts in the urine, with general dropsy and a heart evidently greatly enlarged, with much shortness of breath. Of these symptoms, to individualize them, there are none which have anything like the grave significance of enlargement of the heart with heaving impulse and constant shortness of breath; people with this combination seldom live more than a few months. Experience has long since taught me to believe that the presence or absence of the signs of valvular change are, comparatively speaking, of very secondary importance, and should have little influence in determining our decision of the probable duration of life, but that all our efforts should rather be turned to endeavor to form an estimate of the size of the heart and state of its walls.

*Treatment.*—It would make this paper much too long if any attempt was made elaborately to discuss the treatment; besides which, the question does not properly come under its scope as defined in the title. It need, therefore, only be said that the disease is so wide-spread in its results, and produces such varying effects as the morbid process takes possession of one or another part of the organism, that no special plan of treatment could be laid down which would cover all the different aspects it may present. Drugs which have seemed to me to be capable of effecting much good in certain phases of the complaint are carbonate of ammonia with small doses of digitalis—these should be given three or four times a day, and their use persisted in for long periods, often for as much as a year or more. The advantages of this mode of treatment were exemplified in Case XVII.

*Pathology.*—As was stated, the pathology of this disease has been discussed by me in papers already published, and time fails, nor would it perhaps be desirable, to go fully over the subject again. There are, however, a few points to which allusion must be made. To my mind it seems established as a fact and beyond the reach of doubt that many cases of chronic Bright's disease, if not most of them, are in truth cases of arterial disease; this was years ago asserted by Gull and Sutton; now, as a result of more recent investigation, I believe it to be established that endarterial inflammation is an important part of the disease. In reaching this conclusion one more step has been made in the direction of a final understanding of the process, though whether we are now near to this goal or still far away is a question which the future only can determine.

It would be easy, but of no present advantage, to speculate upon whether the endarterial inflammation is but an extension of disease from the blood, the living and moving tissue with which the lining of the arteries is always in contact, or whether the process starts in the

[1] Chronic Bright's Disease (Arterio-capillary Fibrosis) in its Relations to Insanity, by E. A. Christian, M.D. The Journal of the American Medical Association, March 23, 1889.

[2] On Changes in the Spinal Cord and its Vessels in Arterio-capillary Fibrosis. Trans. Path. Soc. London, vol. xxviii., 1887.

connective tissues, in which the arteries lie and of which they are in fact a part, or whether again the inflammation has its true origin in the arterial intima. The probability is that the future will show the arterial inflammation to be but an extension and consequence of some other pre-existing change. Outside of the assertion that the disease begins in the blood—and this is a theory which, though exceedingly plausible and not unlikely to be correct, is without a single fact of observation to establish its truth, so little understanding have we at the present time of the blood or its diseases—there has as yet been but one hypothesis offered to explain an earlier beginning of the disease. This hypothesis—for hypothesis only at present has it a right to be called—was mentioned in one of my earlier papers (loc. cit.), and is that which was in the first instance propounded by Drs. Da Costa and Longstreth,[1] and has been further elaborated by Dr. Da Costa in a later paper.[2] These authors, after making post-mortem investigations both macroscopic and microscopic, assert that there is constantly present a lesion of the renal nerve plexus, and Dr. Da Costa in his later paper states that lesions were also found in the cardiac ganglia in cases of Bright's disease. These investigations are of the highest scientific interest and exceedingly suggestive, for, from a purely theoretical point of view, it is fully as reasonable to suppose that the morbid process might begin in the nervous system as in the lining of the arteries or elsewhere. Investigation of the histological condition of the nerve-trunks and ganglia of the sympathetic system offers a field of the greatest interest, but at the same time great difficulty, for, if the truth be told, but little is really known at the present time of its ordinary condition in human adults—that is to say, few, if any, pathologists have been in the habit of examining the sympathetic so frequently as to be very familiar with its ordinary condition. Further study of this matter is much to be desired, but even if such investigation should demonstrate that a lesion of the sympathetic is as constantly present as the endarteritis, it would still remain an open question which, if either, was the causative lesion.

A point of great pathological significance, and to which allusion has already been made, is that valvular disease of the heart, as recognized by the ordinary clinical signs, may come on in the course of this disease without the patient's having at any time an acute attack of illness, and this is proved by what took place in Case IV., the woman developing valvular heart-lesion in the course of an attack of mild chronic Bright's disease lasting two years, during which time she had no severe illness or febrile attack—at the beginning being free from valve change, and now having its clinical evidences most unmistakably developed; showing, it seems to me, most positively that the endarterial inflammation has crept into the heart to twist and distort the valve.

It is a curious fact, and one worth recording, though at present I can offer no explanation nor draw any deductions from it, that in several different sorts of tissue removed by operation by surgeons as incurably diseased, I have found upon microscopic examination precisely the same endarterial inflammation and thickening, in some vessels so great as to entirely close their calibre, as found almost universally throughout the body in the cases of chronic endarteritis or chronic Bright's disease that have been described. These have been ovaries and Fallopian tubes removed by gynecologists, a vulvo-vaginal retention cyst, a cancerous uterus, and I think other tissues.

The relation of old age to this process of chronic endarteritis, or Bright's disease, I have discussed in former papers, and it does not seem possible longer to doubt that the conditions are in many respects parallel, if not identical, and a further confirmation of this view is afforded by the observation I have recorded, that a similar condition of the lining of arteries has been found in the heart of an infant dying of marasmus at five months of age (see Fig. 4). The arteries of young infants, just as all the rest of their tissues, present histological appearances which are different from those of adult life, and they may offer, therefore, perhaps an opportunity to learn the true origin of this process of atheroma, as it has been called, which could never be had from the study of adult tissues. The plicated membrane or fenestrated membrane of Henle presents itself in the arteries of young infants, when examined in cross-section, as a folded line somewhat thicker relatively than it is in the tissues of older persons, and in healthy vessels appears to be entirely structureless, containing no nuclei which will take stain; in the diseased artery from the heart it seems as if this had, owing to some irritation, become inflamed, and there are many proliferated nuclei in the membrane itself, or lying inside of it, producing swellings in the lining of the artery, just as is so commonly seen in the atheromatous processes of adult life (see Fig. 4). It is impossible to avoid drawing a parallel between these appearances and what is so well known and has been so much studied in inflammation of the cornea.

The drawings were made for me by Dr. B. A. Randall, and they admirably represent the appearances intended to be shown. As they were to be reproduced by photographic process, they were necessarily made somewhat diagrammatic, for many of the finer lines and shadings in a drawing cannot have justice done them by the photographic method as here applied.

It was my desire in this paper to deal more with the clinical than the pathological side of the subject—to try to formulate the symptoms so that a diagnosis may be more easily made; and last, though by no means least, it is high time to give the disease a name, so that it may be commonly recognized and admitted to our every-day classifications of diseases. To me it seems plain enough, in the present state of clinical and pathological knowledge, that the morbid process is "chronic endarteritis"—and so the disease should be named.

## COSTO-CHONDRAL LUXATION OF FIRST TO SIXTH RIBS, BACKWARD,

### With Partial Dislocation of Right Clavicle, Upward and Backward.

By ALFRED E. BRADLEY,

ASSISTANT SURGEON, U. S. A.

H. H——, a recruit, aged twenty-six, who had always been perfectly healthy, enlisted in Boston, February 14, 1889. While en route for the recruiting depot, on February 16th, he was struck and injured by a passing passenger train in the following manner: With a companion standing at his left, he was on a narrow platform, backed closely against a wall of masonry, awaiting the passing of a train which came on to them suddenly and unawares while at this point.

The train approaching toward his left passed without touching either him or his companion, until the last coach, presumably a sleeper, came up to them. This coach was rocking or swaying from side to side, and they state it was wider than those which preceded it. At all events, as it passed it struck H——'s companion, a large, powerful man, on the left shoulder, threw him forward, and carried or rolled him around H—— in such a manner as to forcibly crowd and jam them both against the wall behind them. The force was thus expended in a rotary manner. After being thus rotated and jammed against the wall, they fell to the ground, and sustained no further injury.

They were conducted to a railway station about half a mile distant, H—— suffering but little at that time, while his companion was in acute pain, due, as was afterward ascertained, to fracture of the second and third ribs on the

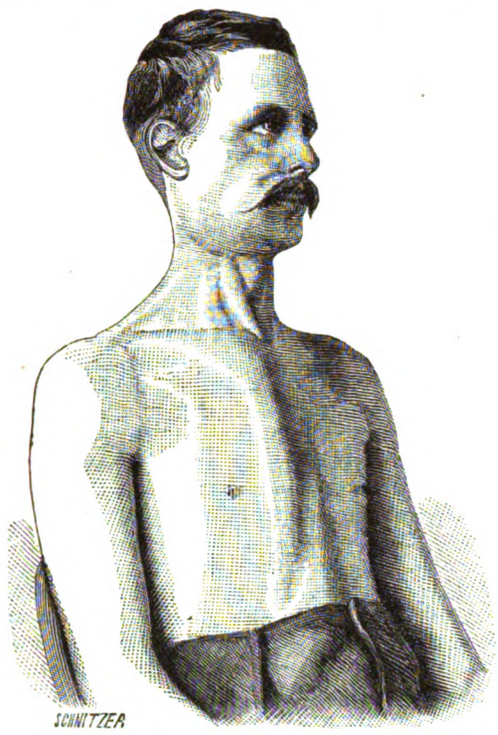
left side, with traumatism of the lung, as evidenced by the expectoration of blood. As his case is not further connected in any way with this article, suffice it to say he made a perfect recovery.

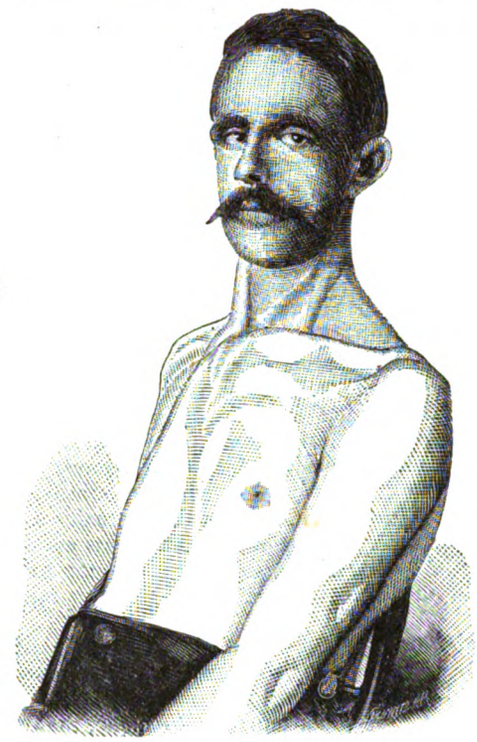
H—— was bruised about the head and face, and after a careless examination by a physician at the station, was informed he "would be all right in a few minutes."

Soon after, however, he began to experience much difficulty in breathing, and great pain in the right chest, this being his first intimation of any injury more serious than the bruises above referred to. The writer saw him about half an hour later, and his condition then was as follows:

There existed a condition of mild shock, with a feeble pulse, considerable pallor, and a temperature of 97°.

He complained of great difficulty in breathing, and pain in the right chest. Whiskey and aromatic spirits of ammonia was administered in repeated doses, and on his





recovering somewhat from the shock, careful examination elicited the following rare, and one might say unique, injury. On baring the chest, the eye of the observer was at once arrested by the striking asymmetry that was presented.

At the right of the sternum, which seemed to be tilted or turned on its long axis from left to right in consequence of the asymmetry, a linear protrusion was seen, which was easily ascertained to be caused by the over riding of the costal cartilages on their respective ribs.

The ends of the ribs were depressed, and the protruding chondral articulating surfaces were made out by palpation to form nearly a straight line from above, downward and outward. Careful examination disclosed the fact that all the ribs on the right side, from the first to the sixth inclusive, were dislocated backward from their chondral articulations. Further examination showed that the sternal end of the right clavicle was also partially dislocated upward and backward.

The supra-sternal notch was partially obliterated, the sternal end of the clavicle was quite mobile, seemed almost free from its sternal attachments, and could be easily reduced; though the reduction was but temporary, it soon resuming the former position, as evidenced by the fulness to the right and above the sternum and the partially obliterated supra-sternal notch. The lungs were in a condition of mild emphysema, but there was at no time any expectoration of blood.

All efforts to reduce the dislocated ribs proved futile. Both shoulders had been drawn backward, and the right arm rotated outward to put the pectoral muscle on the stretch; but owing to the sternal and chondral insertions of this muscle (as well as its costal) this proved ineffectual.

Extreme extension of the spine over a roll of pillows in the dorso-lumbar region was then tried.

An effort was made to reduce by forced inspiration, but it was impossible for the patient to properly execute this procedure, owing to the pain and extent of the injury.

All efforts to produce reduction having failed, this dressing was then applied. For the partial dislocation of the clavicle the right shoulder was drawn backward in such a manner as to retain the head of the bone in the proper position, and there held by means of broad adhesive strips applied much after the manner of Sayer's dressing for fracture of this bone. For the luxated ribs a wide, thick pad over the seat of injury, and broad adhesive strips were used encircling the chest, also passing from front to back over the right clavicle to give that bone additional support. The right-arm was then brought to the side of the chest after placing a generous pad of cotton wool in the axilla, and there fixedly retained by a broad roller passing around the whole chest. After the application of this dressing the patient expressed himself as feeling very comfortable, and in little or no pain.

On the following day there existed considerable dyspnœa, profuse frothy expectoration, and loud bronchial and tracheal râles. He was given an ounce of sulphate of magnesia, and ordered five grains of carbonate of ammonia in three drachms of liq. ammon. acetat. every two hours. His temperature was normal.

February 19th.—Was considerably easier; temperature morning and evening, 99°; respiration less difficult, but there still existed considerable pain in the chest. Pulse 90; was ordered half an ounce of whiskey to be given every four hours.

February 20th.—Was somewhat improved as to pain and expectoration. Morning and evening temperature 99.4°. He was given gr. $\frac{1}{4}$ of morphine at night.

February 21st.—Morning temperature, 100°. Evening, 100.2°. Was given three drachms of Rochelle salts and gr. $\frac{1}{6}$ of morphine in the evening.

On the 22d his temperature was again 100°, but never afterward reached that point.

Excepting a more or less continuous dyspnœa, the pa-

tient made no complaint of pain, more than a general uneasiness or soreness at the site of injury. On the 24th he became very short of breath, and loud bronchial and tracheal râles were again heard, and death seemed threatened by œdema of the lungs. He was ordered half-ounces of brandy in four ounces of milk, and five grains of carbonate of ammonia in half an ounce of liq. ammon. acetatis, alternately every two hours, with occasional doses of morphine for the restlessness.

This had the happy result of a speedy return to a comparatively normal respiratory action, and from this time on his progress toward convalescence was uninterrupted.

On March 10th the dressings were removed, and were found to have answered admirably for the purpose for which they were intended. The clavicle had been held well and properly in position, and it was seen bone callus had been freely thrown upward from the fractured first cartilage, but not in sufficient quantity to impede the motions of the clavicle to any degree.

At the present writing recovery is complete as far as repair is concerned. The motions of the arm seem to be in no manner impaired, and the sterno-clavicular articulation in normal condition, though the deformity resulting from the costo-chondral dislocation is marked, and is quite well shown by the cuts, from photographs recently taken.

The following measurements, taken since recovery, show to what extent the uninjured differs from the injured side of the chest.

At the recruiting rendezvous, the recruiting officer had taken measurements just on a level of the angle of the scapular, and gives them as 34 and 36½ inches respectively, as the circumference during forced expiration and forced inspiration. As these were taken hurriedly, and probably with not much accuracy, they cannot be depended upon. However, it is well to know these former measurements in relation to measurements taken since recovery, as the latter show but 32 and 34½ inches, respectively. It is hardly probable that such a difference actually existed, though undoubtedly the respiratory action was enough involved by the results of the injury, to account for considerable of the discrepancy between the two measurements.

Furthermore, from the spine to the middle of the sternum on the right side, it is now 16 inches forced expiration and 17 inches forced inspiration; and on the left over the same region, the scapular angle, the dimensions are respectively 16 and 17½ inches.

From these measurements, and by careful inspection and palpation, it is believed the over-riding of the cartilages is between ¼ and ½ an inch. From the middle of the sternum to the end of the protruding second cartilage is 1¾ inch; to the end of the fifth cartilage is 2⅝ inches.

As far as can be ascertained the union is osseous, as is usual in injuries to these cartilages.

While the cure is by no means a perfectly satisfactory one, viewing the remaining deformity, it is nevertheless most gratifying for the patient to have escaped with his life, after having been subjected to a compressive force necessary to have caused so extensive and serious an injury. It now gives him no inconvenience whatsoever, and were it not for the remaining deformity, nothing would remain to evidence so serious an injury ever having been received.

It is impossible, of course, to predict exactly what influence the impaired capacity of the right chest will have over the development of any possible pulmonary trouble in the future. It is also highly probable, that any work in the future which may call into active service the injured parts, such as heavy lifting or any prolonged strain, will undoubtedly be followed by evidences of weakness, and more or less loss of power to the parts implicated.

After a painstaking search, it is found that the literature of this injury is very meagre indeed, but few cases similar ever having been recorded, and still less in number ever having been accurately described. As there is no synovial membrane or articulation proper between the ribs and costal cartilage, but simply a fusion of the two, it is still a question as to whether this injury can be correctly termed "dislocation," or if it is in reality one of fracture. It is true that it is difficult to distinguish between a true fracture of the cartilage, an injury as rare as the one under consideration, and a separation of a rib from its cartilage.

In the case described in this article, it seems that the evidence is conclusive as to the character of the injury. The line of separation downward and outward, the measurements as compared to those taken on an osseous skeleton, and on the uninjured side, the age of the patient —all seem to, nay do, make it an undoubted case of separation of the ribs from the cartilages, call it luxation or fracture as we please.

Alfred Poland, in Holmes's "System of Surgery," vol. ii., p. 570, submits a table of four cases, the fourth of which, from the remarks here given, seems almost exactly similar to the case herein described. It is the famous case reported by Charles Bell, caused by pressure between a post and a carriage; it is said "the majority of the ribs were luxated on the cartilages," and any more definite details the writer has failed to find. In the writer's case six ribs on one side are luxated, caused by circumstances strikingly similar to Bell's, pressure by a passing railway coach against a wall.

It was not stated what treatment was used, or what result followed, in Bell's case. In the *Lancet*, 1882, vol. i., p. 432 (*Index Medicus*), a case is said to be reported by Mulvaney in which the left costal cartilages were dislocated backward (from ribs or sternum?), accompanied by a dislocation of the right clavicle forward.

The writer has not had access to that volume of the *Lancet*, and is uncertain whether it was a costo-chondral, or a chondro-sternal luxation, the title of the article, as given in the *Index Medicus*, not designating.

Careful investigation indicates that the cases recorded in Holmes's "Surgery" by Poland, above referred to, four in number, are the only authenticated cases of dislocations of the ribs upon their cartilages.

This conclusion is also reached in an admirable paper by A. W. Blodgett, in the *New York Medical Journal*, vol. xxxviii., 1883, pp. 34-62, in which are reported and discussed cases of injury to the cartilages, more especially, however, the chondro-sternal luxations. The case now reported by the writer swells the number to five, and should the case of Mulvaney prove to be costo-chondral instead of chondro-sternal, the number to six.

It is stated that the most constant symptom of this luxation is the prominence of the chondral end of the ribs in advance of their corresponding cartilages, while in the case under consideration the conditions are reversed.

Undoubtedly this injury is usually or always the result of violent compression of the chest.

Where the cartilages over-ride, compression would seem to probably have been lateral; where the ribs over-ride, it would seem to have been antero-posteriorly, or in the recorded cases upon the sternum.

DAVID'S ISLAND, N. Y. H., May, 1889.

---

BLONDES.—The process of training for a "blonde" was in Venice, in the sixteenth century, a somewhat serious one. The aspirant took dragon's blood (*i.e.*, the resinous gum of the dragon-tree), ashes, egg-shells, sulphur, orange-peel, and sundry other trifles, all of which she boiled into association over a fire. With the essence of this mixture she assiduously bathed and sponged her hair. When her locks were deemed to be saturated sufficiently to dry them, she was wont to ascend to the roof of the house, and there sit in the sun, with a straw zone like the detached brim of a hat fastened round her head, to protect her from solar inconvenience. The result is said to have extracted admiration even from Moslem strangers.—*Medical Press.*

## AN EXPERIMENTAL STUDY OF THE BROWN-SÉQUARD THEORY.

By HENRY P. LOOMIS, M.D.,
NEW YORK.

The position which Dr. Brown-Séquard has held and still holds in the scientific world entitles any theory advanced by him to the respectful consideration of the profession. The recent one, relating to the use of injections of testicular liquid, was properly presented through reputable professional channels, and supported by experiments continued through a considerable period of time, and repeated and confirmed by other observers. Unfortunately, there has since been engrafted upon it much that has no shadow of foundation in any contention of the originator, and it has received a public and unprofessional notoriety which is not only to be regretted on general principles, but may possibly long prejudice us against any merit that it may actually possess. A brief review of his proposition is advisable.

The following is a fair statement of the physical effects of the treatment as applied by Dr. Brown-Séquard to himself:

From a condition of weakness, small appetite, and sleeplessness, he entered into one of comparative physical and mental strength. No record of the influence upon the appetite or capacity for sleep is given. He attributes these changes to an increase in the power of the nerve-centres, and notes, upon a cessation of the injections, and after a period of four weeks, during which no marked change occurred, a gradual reversion to his former state. He denies that the beneficial effect is due to any personal idiosyncrasy, as experiments conducted by Dr. Variot independently of himself, upon five elderly men, produced similar results.

The conclusions he draws are:

1. That the spermatic fluid is potent to increase the strength of the human organism, presumably in old men, not by structural change, but by nutritive modification.

2. That the alterations in muscular structure not essentially allied to old age may disappear, and a consequent recovery of former power by the tissues may supervene; and,

Finally, that the subject is well worthy of further experimental investigation.

In further definition of his position, Dr. Brown-Séquard specifically affirms his continued belief in the fatality and irreversibility of those nutritive actions which produce the changes of advancing age, and acknowledges that the facts presented are insufficient to solve the question of possible structural change in muscles, nerves, and nerve-centres.

I can see nothing in this to support the accusation that he claims to have discovered the source of perpetual youth, but rather a flat denial of any such contention, as though, in making his affirmation, he recognized the danger of misrepresentation and made an effort to provide against it. What he does claim is the discovery of certain physical changes wrought by the injection of the mixture; that it was apparently beneficial in its action with possibilities of becoming more so, and that the phenomena were important enough to invite careful study and analysis. At all events, my experiments have been made with such interpretation of the proposition, and the deductions given below are the present result.

Following Dr. Brown-Séquard's instruction, and always observing strict antiseptic precautions, I crushed in a mortar a small portion of the tissue of the testicle of a two-year-old ram, mingled with an equal quantity by bulk of distilled water.

The resultant mixture, after infiltration, disclosed under the microscope albuminous granules and crystals of spermine that are formed of a phosphate of an organic base, but no bacteria or spermatozoa. Thirty minims constituted a dose, and fresh material was prepared on each occasion. Not more than an hour was allowed to elapse between the death of the animal and the operation.

Within the last three weeks I have injected fluid of this character into a number of men, with the following results.

Class I. includes only such as were patients in Bellevue Hospital, who had no knowledge or suspicion of the character of the liquid, and took no medicine during the period of experimentation.

Case I.—Charles G——, aged fifty-six, shoemaker, had been under treatment in Bellevue Hospital for a month, suffering from emphysema, chronic bronchitis, and asthma. By treatment, his chronic bronchitis had been cured, but his asthmatic attacks still continued, coming on generally in the early evening. The patient was given four injections of thirty minims each of the fluid, at intervals of two days. A short time after the first injection he said "he felt as if he had taken a big dose of morphine;" that night he was not troubled with his asthma, for the first time in over a month. During the following day he felt much better, stronger, and with increased vitality. This improvement continued and increased up to the time of the fourth injection. After the fourth injection, although the patient complained of no pain at the seat of puncture, still for the twenty-four hours following the injection his general condition seemed to be much worse, his hands trembled, he complained of a burning sensation, and appeared as one who had suffered a severe nervous shock. At the expiration of the twenty-four hours his condition became substantially as it was preceding the last injection. The return to this condition took place about a week ago, since which time no injections have been administered. The seemingly beneficial effects have gradually worn off, accompanied by a slight return of his asthmatic attacks and loss of strength.

During the time of experimentation no change was noticed in his pulse, which ranged between 62 and 70. His respirations at the time of the first experiment were 24, after the first injection they remained about 20. The dynamometer moved by the flexors of the right forearm registered 59 as against 50 prior to the injections.

*Comments.*—During the period of experimentation the patient's asthma improved, his respirations became less frequent, his strength increased, and his general condition was better. The improvement in the patient has not been permanent.

Case II.—William D——, aged sixty-two, a tailor, sufferer from chronic diarrhœa, general debility and senility, while not actually on the sick list at the time of experimentation, had been in no particular materially benefited by treatment. He received four injections at intervals of three days. The day following the first injection he acknowledged that he "felt better," but attributed his condition to an improvement in his diarrhœa. After the second and third injections he affirmed that he "felt much better, livelier, and clearer in his head;" "that he was much better able to go about his work."

His pulse during the period of experimentation remained at 64, respiration at 20, and strength, as registered by the dynamometer, at 60.

*Comments.*—The patient's statements of his improved condition were fully within the apparent facts.

Case III.—Matthew M——, aged seventy-seven, a sufferer from senility, was under special treatment for diarrhœa, which had lasted for about three weeks and had been controlled by appropriate remedies. He received three injections at intervals of two days, the first being given, as in other cases, at about 5 P.M. By the patient's own statement, his improvement began to be noticeable on the morning following the first injection. His words in describing his condition were, that he "felt much livelier and better," and the testimony of the attendant physicians and nurses was to the same effect. The estimate of the improvement in this case is much more emphatic than in the others. The pulse was variable both before and during the period of experimentation, marked increase, however, being observed during the twelve hours immediately following the injection. Res-

piration, which prior to the injection had averaged 16, then rose to 20. The registration on the dynamometer showed an increase from 38 to 42.

*Comments.*—I regarded this case as the one best calculated to test the efficacy of the fluid. The improvement, while in no way sudden or extraordinary, has been steady and decided. As insufficient time has elapsed since the last injection, it is premature to estimate the permanency of the improvement.

CASE IV.—G. D——, aged fifty-two, a sufferer from chronic rheumatism, received a single injection without general or specific result.

CASE V.—John C——, aged fifty-seven, seaman, had been suffering for three weeks from the exacerbation of a chronic rheumatism. He received two injections of 30 minims each with an interval of forty-eight hours. Not only was no improvement noticed, but rather an increase of symptoms.

Class II. embraces, with one exception, private cases. All were men of intelligence and education, and were familiar with the theory and method of treatment.

CASE VI.—L. K——, aged forty-eight, with a neurotic family history, suffered from an entire loss of sexual appetite, due no doubt to excesses in early life. He complained of loss of memory, insomnia, and despondency. He had had no erection since last March. Two injections of 30 minims each, with an interval of three days, were given him without result.

CASE VII.—George D——, aged thirty-five, was a sufferer from no organic difficulty, but was a typical nervous case, and had consulted many physicians with no improvement, as he thought. He was confident this remedy would effect his permanent cure. He received four injections at intervals of two days, with a marked increase of nervousness. He seemed to be made worse by the treatment.

CASE VIII.—Doctor M——, aged fifty-seven, suffered for the past five years from constant anæmic headache; with this exception he was perfectly well. As he had obtained no relief from medication, he requested me to give him an injection. He derived no appreciable benefit from the injection, and his headache was not mitigated.

CASE IX.—J. A. R——, aged thirty-six, a sufferer from what his physician diagnosed as chronic muscular rheumatism, obtained no improvement from two injections.

CASE X.—X. Y——, aged forty-seven, had suffered for five years from a peculiar nervous disease which had been diagnosed, by some specialists in Europe and this country, as locomotor ataxia. As this gentleman has education and exceptional ability, and is free from all prejudice in regard to the treatment, I give his own description of the effect of the first injection, which was administered at 6 P.M. "I noticed no sensation," he said, "until 7.15 the same evening. Then a comfortable feeling came over me, as if I had taken a glass of champagne; in a word, I felt rested. On retiring, at nine o'clock, I noticed some soreness in my leg, in the region of the puncture. From this time until 2 A.M. I suffered from most peculiar sensations. I was very restless and nervous; my body felt as if it were burning up, my mouth was parched, and my face flushed. My wife, thinking I must have a high fever, took my temperature, but found it normal. At this time I was wide awake and my mind active. Most of the time I was unable to control the shaking of my hands. I slept from two o'clock until eight, when I awoke somewhat refreshed, and found that the soreness had left my leg. All the forenoon I felt seedy, but by afternoon I began to improve, and by evening I felt better than I had for months, stronger, and with more ambition. This effect has continued up to the present time (two days).

This patient is now under treatment, and has had four injections, but I can see no improvement in his disease. His gain, if any, is purely subjective.

I have received a number of reports of cases from physicians to whom I have furnished the fluid. Some of them state that there has been a wonderful improvement in their subjects. As, however, these cases have not fallen under my personal observation, I refrain from noting them. My observations upon the cases are as follows:

I. *a.* I can see no reason to anticipate danger of septicæmia from the use of the fluid prepared under proper antiseptic precautions, provided the material used be absolutely fresh and free from all trace of disease. My attention was called to the necessity for the closest scrutiny in this last particular, by having discovered, in specimens taken from an apparently healthy ram, a solitary tubercle in which were demonstrated tubercle bacilli. In none of the cases have I seen any bad results, and only in a few has there been a moderate amount of pain at the point of injection, lasting from six to eight hours.

*b.* I can explain the singular nervous affection apparent in certain of the cases only on the theory that upon the nerve-centres the mixture exerts some powerful but as yet unexplained influence, which, even if its use be eventually proved beneficial in some cases, must render its employment in others a matter of caution. It is far from safe to say and proceed upon the belief that "if it does no good it can do no harm."

II. *a.* I seem to see in almost all the cases of *old men* subjected to the experiment an increase in strength and vitality which certainly persists for several days. I have noticed nothing in the least resembling the secondary depression which so commonly follows the use of ordinary stimulants.

*b.* When used in cases of actual disease no modification of pathological conditions or processes has been recognizable.

I therefore conclude:

1. That the injection of this testicular mixture does, as claimed, produce "nutritive modification" in the tissues of elderly men, due probably to the stimulation of the nerve-centres.

2. As far as my own experiments are concerned, sufficient time has not yet elapsed to justify an affirmation or denial of the correctness of Dr. Brown-Séquard's second conclusion.

3. There is in the theory sufficient ground for further experimentation.

---

## CONTRIBUTIONS TO THE SUBJECT OF TUMORS OF THE ORBIT AND NEIGHBORING CAVITIES.[1]

BY CHARLES STEDMAN BULL, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF THE CITY OF NEW YORK; SURGEON TO THE NEW YORK EYE INFIRMARY; CONSULTING OPHTHALMIC SURGEON TO ST. LUKE'S HOSPITAL.

CASE I. *Aaeno-sarcoma of the Lachrymal Gland.*—The patient, George G——, aged thirty-five, presented himself to me for the first time on May 30, 1887, with the following history: A little more than a year before he had noticed a swelling or tumor, as he thought, of the outer angle of the left upper lid; but after a while he discovered that the swelling was not in the lid, but was a tumor beneath the lid, and on the outer aspect of the left eye. There was at first no interference with the movements either of the lid or globe, and no sense of discomfort; but the tumor gradually increased in size and began to cause the patient some annoyance. It had never been painful nor especially sensitive on pressure, nor was there any interference with the vision. When I saw him, the outer end of the left upper lid was somewhat bulging, and the growth was seen to be applied closely to the eyeball on the upper, outer, and lower quadrants, and presented in the interpalpebral opening. On everting both lids, and making the patient look toward the extreme right, the growth was seen to extend backward and upward into the orbit, and to be connected with a glandular tumor at

[1] Read before the American Ophthalmological Society, at its Twenty-fifth Annual Meeting, New London, July 17, 1889.

the site of the lachrymal gland. The tumor was distinctly lobular, reddish in color, somewhat firm in character, and perfectly movable beneath the ocular conjunctiva and upon the globe. The motility of the eye was slightly interfered with upward and outward. The media and fundus were normal, and vision was $\frac{20}{20}+$. The ocular and palpebral conjunctiva was somewhat injected, but there was no secretion of any kind. A diagnosis was made of tumor of the lachrymal gland, and it was decided to attempt its removal. The patient was etherized, and the upper lid pulled downward as far as possible over the lower lid. The eyebrow was then closely shaved, and an incision was made from the middle of the eyebrow outward, following the line of the supra-orbital margin for the distance of an inch and a half, through the skin and subcutaneous tissue. The tarso-orbital fascia was then divided, care being taken not to wound the tendon of the levator palpebræ muscle. As soon as the orbital cavity was opened and some of the orbital fat pushed aside, the tumor was seen to involve the lachrymal gland. By the aid of the handle of the scalpel and a pair of blunt-pointed scissors the adhesions between the growth and the upper and outer walls of the orbit were carefully divided, no very firm points of adhesion being found. The attachments of the tumor to the eyeball were then easily separated, care being taken to dissect off as much of the ocular conjunctiva from the external face of the tumor as was possible, and the enlarged gland was then removed entire. There was considerable hemorrhage from the divided vessels, which, however, soon ceased, and the cavity was then washed out carefully with a solution of mercuric corrosive chloride (1–1,000). Six deep sutures were then introduced through the entire thickness of the lips of the wound, including the tarso-orbital fascia, and as many more through the external lips of the wound as were necessary to bring the edges into thorough coaptation. Sublimate dressings and a bandage were then applied. The wound healed by first intention, and there was no suppuration, and in three weeks all signs of tumor or operation had disappeared. The tumor was hardened in Müller's fluid and alcohol, and numerous sections were made and carefully stained for future study. These showed that the degeneration had begun near the centre of the gland, for here nearly all traces of the normal glandular structure were absent. It was impossible, however, to determine whether the abnormal growth began in the ependyma of the glandular tubules or in the connective tissue around them. If it be true, as Berlin thinks, that all adenoid tumors belong to the common type of cylindroma, then the tumor in question was a cylindroma. Away from the centre, and near the periphery of the gland, there were found many tubules in a healthy state, but even in the midst of these normal tubules were others in a distinct condition of hypertrophy, with numerous small round cells. In all parts of the growth, the connective-tissue framework was crowded with small round cells, and as the sections approached the centre of the gland these cells became more and more numerous, until all the glandular elements were crowded out and disappeared, and nothing was visible but a closely pressed mass of small round cells in place of glandular tissue. After a careful examination had been made of the various sections, the patient was told that the growth would in all probability return, and that he must report at intervals for examination. The tumor was removed in June, 1887, and the patient has been seen at intervals of two or three months ever since, the last time in March of this year. At this visit nothing abnormal was discovered in the orbit or eyelids. I have termed the growth an adeno-sarcoma of the lachrymal gland, as being most in consonance with the results of the microscopic examination.

CASE II. *Abscess of the Ethmoid Cells, Frontal Sinus, and Orbit.*—The patient, a gentleman, aged forty-six, consulted me on April 16, 1888, with the following history: He had been long subject to naso-pharyngeal catarrh, with frequent acute exacerbations and profuse discharge, and he had been under treatment of one kind or another for many years. About Christmas of 1887 he first noticed a swelling at the upper and inner angle of the right orbit, though he had had a constant dull pain in this vicinity for more than a year. The swelling continued to slowly increase, without much change in the subjective symptoms, until March, when he began to see double. At this time his headache was constant, and being alarmed he consulted his family physician, who made an examination and discovered that with either eye alone his vision was perfect, but that the diplopia, and consequent disturbance of vision, returned when both eyes were open.

Tincture of iodine was painted over the swelling of the lid, and potassium iodide was given internally, but without producing any beneficial effect, and he was finally advised to consult me, which he did on April 16, 1888. I found a rather marked protrusion of the inner half of the right upper lid, and a dislocation of the right eye outward and downward, and a little forward. The motility of the eye inward and upward was somewhat limited. The lids were normal in action. Vision was $\frac{20}{20}+$, and the media, fundus, and field of vision were perfectly normal in every respect. The tumor or swelling was smooth, elastic, irregularly ovoid in shape, and extended backward some distance into the orbit. It occupied the supero-internal angle and inner wall of the orbit. It was painless on pressure, and showed no signs of any inflammatory process. There was a profuse, almost purulent, discharge from the right nostril. A hypodermic needle was introduced through the skin of the lid, and pus was withdrawn from the cavity. A diagnosis was made of abscess of the frontal sinus, which had probably broken through the bony roof of the orbit, and involved the latter cavity. The patient was told that nothing but operative interference would be of any use, and he consented at once to have the operation done. On April 18th the right eyebrow was shaved, and a long incision was made through all the tissues down to the bone, beginning at a point at the junction of the middle and outer thirds of the eyebrow, and running parallel to, and just above, the supra-orbital margin, across the root of the nose, to the inner end of the eyebrow on the opposite side. As soon as the knife penetrated the region of the swelling it was followed by a flow of pus, amounting to about half an ounce, as nearly as could be calculated. As soon as the incision was completed the knife was withdrawn and the finger introduced. A large irregular hole was felt just at the inner end of the supra-orbital margin, extending into the frontal sinus, and involving part of the lachrymal bone. Pressure on the closed lids backward caused pus to run from the incision, and the finger pushed into the orbital cavity discovered that the abscess extended backward into the orbit, and that there was an opening in the orbital plate of the ethmoid bone large enough to admit the end of the middle finger. The walls of the frontal sinus were distended in all directions, and were rough and covered with numerous osteophytes; but the bony septum between the frontal sinuses did not appear to be perforated. The frontal sinus was first washed out with a sublimate solution (1–500), bringing away much pus and small particles of bone, and after a brief period the fluid was observed to drop from the right nostril, showing that a communication existed between the frontal sinus and the superior nasal meatus on this side. The same solution was then used to wash out the cavity of the abscess in the orbit, and also the ethmoid cells, and this also brought away a large quantity of pus. After the entire cavity had been cleansed thoroughly, a rubber drainage-tube was introduced into the frontal sinus, and the rest of the external wound kept open by pledgets of sublimated cotton, and the patient was made to lie on his right side. The lids were kept closed, and covered by a piece of gold-beater's skin, in order to prevent, as far as possible, any entrance of the purulent discharge into the conjunctival cul-de-sac. The cavity was washed out twice a day with

the sublimate solution, until the discharge of pus grew very scanty, and then the irrigation was practised once a day until all purulent discharge had ceased. The drainage-tube was finally removed at the end of the third week, at which time all external swelling of the surrounding parts had disappeared, the flow of pus was reduced to a few drops, the eyeball had returned to its normal position, and the diplopia had vanished. At the end of the third month the cavity in the orbit had closed, and shortly afterward the external wound along the orbital margin filled up with granulations, which first appeared from the edges of the opening into the frontal sinus, and gradually the external wound healed under a scab. At the end of the fourth month close observation was needed to discover that an operation had been performed. For about two months previously systematic treatment of the nasal cavities had been carried out, with the result of checking all discharge from the nostrils, and converting the patient from the state of a mouth-breather to a condition of normal respiration. The patient has not been troubled since. This is one of quite a number of cases operated upon in a similar manner, which have all recovered in a comparatively short time, and without any bad results.

CASE III. *Tumor of the Maxillary Antrum, Nasal Fossæ, Ethmoid Cells, Orbit, and Cranial Cavity; Operation for its removal; Death.* — The patient, James M——, aged fifty-one, first consulted me on November 11, 1887, and gave the following history: He had always been subject to profuse naso-pharyngeal catarrh, which had been treated in an intermittent and spasmodic manner for a number of years. In February, 1887, he began to suffer from shooting-pains in the left side of the nose, and along the course of the left supra-orbital and infra-orbital nerves, and as the weeks elapsed this pain increased in severity, and began to be localized in the left orbit. In April there appeared a profuse purulent discharge from the left nostril, and from the pharynx. The pain continued to increase in severity, and early in August the left eye began to protrude from the orbit. The ocular conjunctiva gradually became injected, and the eyelids, particularly the lower lid, became swollen. He at this time consulted Dr. E. G. Janeway, of New York, who after a careful examination told him that he had a tumor in the left orbit. The symptoms gradually grew worse, and early in October the exophthalmus was so marked that he could scarcely close the lids over the eyeball, and his vision began to be impaired. On November 11th, when I first saw him, his condition was as follows: The left eye protruded forward, outward, and downward, and the lids could not be closed over it. The cornea was clear. The lower lid was everted and partially concealed beneath the protruding globe. The ocular conjunctiva was markedly congested and the chemosis very extensive. The eye was absolutely immovable. Vision was $\frac{20}{100}$, that of the other eye being normal. The ophthalmoscope showed a well-marked condition of "choked disc," with hemorrhages. A protrusion of the growth could be seen anteriorly at the inner angle of the orbit, and an examination with the finger demonstrated that the tumor could be felt at the inner canthus, and backward along the inner wall and floor of the orbit. A careful examination of the anterior and posterior nares showed that the left inferior nasal meatus was entirely occluded by a growth, and it was thought that the latter also extended into the middle nasal meatus. The occlusion of the inferior meatus was caused by the bones being pushed down from above by the growth, this being the opinion of both Drs. Lefferts and Asch, who kindly examined the case with me. The patient was then sent for a further examination to Dr. William T. Bull, of this city, who diagnosed a tumor of the antrum, nasal meatus, and orbit, and advised non-interference, by reason of the probability that the growth involved the deep bones of the face.

The pain was now so severe that the patient had to be kept constantly under the influence of opiates. By December 3d the eye had become entirely blind, and the protrusion forward of the growth was very marked. It was decided to attempt the partial removal of the tumor, as a means of affording the patient some relief from his suffering. On December 5th the eye was enucleated, under ether, with considerable difficulty, and then complete exenteration of the contents of the orbit was begun. The conjunctiva was divided along the margin of the lids, and the entire contents of the orbit were removed by knife and scissors. The bony floor of the orbit was entirely absent as far back as the apex of the orbit, except a narrow rim along the anterior margin. The maxillary antrum was filled with the growth, and was entirely cleaned out with forceps and curette. The opening from the antrum into the nasal meatus was found enormously enlarged, and the left side of the nose was filled with the growth. Part of the lachrymal bone and the entire orbital plate of the ethmoid were gone, and the ethmoid cells were filled with the growth. There was a large ragged opening through the roof of the orbit into the anterior fossa of the skull, and through this the growth also extended into the cranial cavity. All operative procedures were then stopped, the cavities of the orbit, maxillary sinus, and nasal meatus were carefully washed out with a solution of mercuric bichloride (1–2,000), and antiseptic dressings applied. There was no unusual amount of blood lost during the operation. On recovering from the effects of the anæsthetic the patient complained of great pain in the head, which was relieved by morphia. He remained fairly comfortable until about 9.30 P.M. of December 6th, when his breathing suddenly became stertorous and he was found comatose. In a few minutes the respiration became Cheyne-Stokes in character, but this yielded to hypodermic injections of strychnine. The patient died quietly, in a comatose state, at 7 A.M. of December 7th, with regular respiration. Unfortunately no autopsy could be obtained.

The tumor was carefully hardened in Müller's fluid, for about two months, and numerous sections were then made through various parts of the growth, special care being devoted to the growth removed from the maxillary sinus. At first there was considerable difficulty experienced in classifying the tumor, as the sections seemed to be made up of nothing but cells. Of these there were all kinds—round, ovoid, stellate, and fusiform—the small round cells largely predominating. There was a very scanty fibrillar, intercellular substance, and the general consistency of the growth at the time of its removal was decidedly soft or medullary. This was particularly true of the mass removed from the maxillary antrum. The growth in the orbit and ethmoid cells was decidedly myxo-sarcomatous in character, and a careful study of sections from all parts of the tumor finally led me to class it as a myxo-sarcoma. In some places, in both the orbital and maxillary growths, there were small cavities, filled in the fresh state with a yellowish fluid, which gave to the part the character of a cysto-sarcoma. In all probability the disease started in the maxillary antrum, possibly as the result of long-continued irritation and inflammation extending from the chronic naso-pharyngitis, and thence growing in every direction—inward to the middle and superior nasal meatus, and thence into the cavity of the ethmoid bone, and upward through the orbital plate of the maxillary bone into the orbit. The absorption of a part of the roof of the orbit, and the extension of the growth into the anterior fossa of the skull, was probably the latest stage of the disease. The direction of the growth inward would of course make the extension outward through the opening of the orbit a slow and protracted process, as was proved in this case, the exophthalmus having been one of the later symptoms. Still, it is the general opinion among surgeons that growths originating in cavities near the orbit, and involving the latter secondarily, are generally of very rapid growth. In the case in question all the subjective symptoms occurred within ten months of the death of the patient.

# Clinical Department.

## REPORT OF SIXTEEN CASES OF TYPHOID FEVER, WITH REMARKS.

By O. C. TARBOX, M.D.,

PRINCETON, MINN.

The search for a specific treatment for typhoid fever is not new. Indeed, ever since the disease was first described, and theories advanced concerning its pathology, the aim has been to find a specific for this long-continued, and oftentimes fatal disease. Much has been written, and many remedies advanced as curative.

Just now, when antisepsis governs medical and surgical practice so largely, I desire to report these cases occurring in my private practice as a further testimony to the value of internal antisepsis in the treatment of this fever. While an interne in Randall's Island Hospital, New York City, my attention was called to the treatment originally advocated by Bartholow, viz., by the use of carbolic acid and tincture of iodine. One or two cases thus treated in that institution recovered, but it was not until engaged in private practice that I made such use of the treatment that I could collect statistics of any value.

These cases, sixteen in number, were all treated by the following prescription:

℞. Acidi carbolici..... ♏ xxiv.
Tr. iodinii ..... ♏ xlviij.
Mucil. acaciæ..... ʒ iv.

Of this preparation one teaspoonful, according to age, was given every two or three hours in a little lemonade or ice-water. Little else was given, save antipyrin when the fever ran too high, and a strict milk-diet. Of these cases thus treated, one ended fatally, a girl aged fourteen, who, after having been sick two weeks, was brought to my office from her home, seven miles in the country, an exposure that hastened the fatal issue.

The following are some of the points worth noting. Eight patients had a temperature reaching or exceeding 104° F., two had hemorrhage of the bowels (none fatal), and three had one or more relapses each. One case was complicated by facial erysipelas, occurring in the third week, one by suppurative synovitis of the left knee-joint, and one took by mistake three-fourths of a teaspoonful of carbolic acid (ninety-five per cent.)—a druggist's blunder. This latter case was a boy, aged twelve, who had safely passed through four weeks of fever, and was convalescing nicely when the acid was given to him. His mother's presence of mind in administering some glycerine, milk, and whites of eggs, coupled with a hypodermic injection of apomorphia given twenty minutes afterward by myself, saved his life, though only after a long relapse of fever.

The case of another boy, of eleven years, deserves especial mention from the severity of the disease. The primary fever ran twenty-five days in this case, following which, with a few days' intermission only, were two relapses, one of twenty, and one sixteen days, making a total of sixty-one days of fever. He recovered and with no sequelæ.

Finally, I offer the following propositions as suggesting themselves to me from the above experience, and in the hope that they may be of use to others.

1. It is most rational to produce intestinal antisepsis in this fever, knowing as we do its specific cause to be a germ, and in carbolic acid and tincture of iodine we have prompt and safe germicides. The medicines are quite easily borne by the stomach, if given in lemonade or lemon sirup, and especially after taking some nourishment.

2. By such antiseptic treatment, if given early, I believe the disease is shortened, and the severity lessened. With the exception of the case mentioned above, a rare one in point of severity, all of my cases ran a much shorter course than under former plans of treatment. There was a noticeable absence of those nervous symptoms so common to typhoid fever in nearly all my cases, such as delirium, *subsultus*, carphologia, coma-vigil, and the like. Not one of the sixteen cases had active delirium, requiring restraint.

Constipation was the rule in about every case. Although I have not statistics on that point, I can remember no case in which I was obliged to check or moderate a diarrhœa; oftener mild cathartics or enemas were necessary.

3. The disease is more easily handled, and the danger to others is less by this plan of treatment. In all cases I used, of course, every precaution in that respect by ventilation, frequent change of clothing, and thorough disinfection of the discharges with copperas and chloride of lime, and it has seemed to me I was most fortunate in confining the disease in every instance to the patient, none others taking it. This is an all-important point, and I believe the result was due largely to the intestinal antisepsis. Fortunate we shall be if we shall succeed in preventing the spread of enteric fever in a majority of cases. The above report tends to show, in my opinion, that it can be done.

---

## LIVING TWINS WITH ONE BODY.

Dr. G. M. Collins, of Tipton, Ind., writes: "On Monday night, June 24, 1889, was born to Mr. and Mrs. J——, near Groomsville, Tipton County, Ind., a pair of twin girls with one body. They unite in centre of the body, having but one umbilicus. There are two legs on either side of body. The two children are well formed, and at this writing have every appearance of living. There is a well-formed vagina and anus on either side, between each pair of legs. The two anuses are about one and a half inch apart. Each child has a separate circulation and organism. One will sleep while the other is awake. One leg on each side of the body belongs to each child, that is the same as if two children were lying on their backs with their coccyges in contact, except that the legs are on the sides. At birth their weight was twelve and one-half pounds, and they were twenty-two and one-half inches in length. The bowels and kidneys perform their functions independently. At first the children could bend up and both nurse at once, but now they are developing and do not bend so readily, and one nurses at a time.

"The spinal column is straight, and the two seem to be united at the end of each body. The children are bright and lively, have a fine head of hair and fine features. Their mother is of slender build, and weighs about one hundred pounds."

---

## A PEA IN THE AUDITORY CANAL FOR THIRTY-TWO YEARS.

Dr. W. F. Morgan, of Leavenworth, Kan., reports the following case: Mrs. William H——, German, aged forty, called on July 17, 1889, complaining of her right ear, stating that when eight years old she inserted a pea into each ear; that her mother removed the one in her left ear, but was unsuccessful in her attempts to remove the other, which she believed to be still in the ear. The patient was suffering from vertigo, nausea, and "noises," in her right ear. The watch could be heard only when in contact with the auricle. Hearing of left ear normal. After repeated irrigations, on three successive days, with warm rain-water, and the removal of much hardened cerumen, at the time of her third visit the pea was removed by a Sims uterine tenaculum. It was nearly perfect in form, but very black in color, after its sojourn of thirty-two years in the canal. The watch can now be heard at two feet, and all abnormal sensations have disappeared, except slight soreness of the ear, which will probably very soon entirely subside.

THE MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, August 24, 1889.

## THE SO-CALLED ELIXIR OF YOUTH AND ITS ABSURD PRETENSIONS.

IT is now a little more than a month since the news of Brown-Séquard's alleged method of rejuvenating the aged reached this country. The subject is one that naturally appeals to public interest, since a long life and a vigorous old age have always been among the chief objects of human desire, and consequently it has received a much greater share of newspaper attention than is usually bestowed on medical topics. This is most unfortunate, for the public discussion of such an absurdity tends only to bring scientific medicine into ridicule.

The method is on its face preposterous, its vaunted effects are impossible and ridiculous. It is opposed to all known physiological and biological laws, and had it not been bolstered up by the reputation of a Brown-Séquard, it would scarcely have been heard of outside of the Paris society where it was proposed, and no one would ever have looked upon it in any other light than as the foolish conceit of an old man, in whose mind the dreams of returning youth had assumed the counterfeit of reality. Supported as it was, however, by the weight of an authority hitherto respected in the world of medicine, it was necessary that it should be tested cautiously and in a proper way, and that the method should not be actually condemned until it had been proved as worthless, as were its pretensions extravagant. For unreflecting and obstinate scepticism in matters medical is as illogical as unreasoning credulity.

The experiments reported by Dr. Loomis in another column are sufficient, we think, to satisfy the demands of legitimate prudence. In fact, the subject has already receivedmore attention than it has deserved. The results of these experiments seem to show that the injected material may, in certain cases, act as a mechanical stimulant, but that is all; they fail utterly to support the extravagant claims of physical and mental rejuvenescence which have been put forward in behalf of this method. What these experiments do not so clearly show, since they were conducted with a proper regard for surgical cleanliness, is the imminent risk of septic poisoning or of tuberculous infection to which the subjects of such injections are exposed in the hands of incautious operators.

It is high time, therefore, to call a halt in this matter, unless scientific medicine is to be made ridiculous in the eyes of the public. If there are any not yet convinced of the worthlessness of this method, let them continue their experiments as long as they wish, but let them do so removed from the public gaze and out of sight of the newspaper reporters. It is repugnant to true science to parade such crude and untried theories before the public, as though they had received the stamp of authoritative approval, and in the name of this science we protest against it. The daily press is awakening to the true issues involved, and will in its own effectual way bury the theory out of sight, as soon as its falsity and absurdity have been made manifest.

## MUSCULAR ATROPHY AS A CAUSE OF JOINT PAINS.

ATROPHY of neighboring muscles accompanying, and dependent upon, articular disease, is a fact of daily observation, and as such needs no proof. But, although constantly noted, it is too often regarded only as a symptom, as a phenomenon associated with the joint lesion, and calling for no treatment apart from that bestowed upon the articular disease. It is true that during the progress of the affection the muscular atrophy may properly be ignored, since it can be little benefited at this time. But after the subsidence of the joint disease, the muscles should receive a much larger part of the surgeon's care than they do in most cases.

The importance of treating the muscular atrophy is well illustrated in the histories of several cases related by Dr. Bazy, in *Le Progrès Médical*, No. 12, 1889. In most of these cases there was a history of a sprain of the ankle or knee, followed by some pain and effusion. After a variable period of rest and appropriate treatment, the inflammatory symptoms subsided and the patient was apparently cured. The swelling in the joint disappeared, and passive movements were free and painless. But when the patient attempted to walk the pain returned and persisted, in spite of blisters, the actual cautery, tincture of iodine, etc., as long as any use was made of the joint. Examination at this time showed an apparently normal joint with free passive motion, and without effusion or synovial thickening. Pressure, however, revealed the presence of certain painful points, and these points corresponded almost invariably with the points of insertion of the articular ligaments.

This pain the author refers justly to abnormal traction on the ligaments of the joint, permitted by the weakness of the atrophied muscles. The rôle of the muscles in relation to an articulation is not, M. Bazy contends, strictly that of supplementary ligaments, as many writers hold, but rather that of guiding and directing the joint movements. As long as the muscles are strong and act promptly, the motions of the articulation are normal, and any unusual excursions whereby the ligaments are put unduly on the stretch are prevented. But when the muscles are weak and unable to perform their functions properly, these instinctive directing contractions do not occur, and the joint is subjected to repeated slight sprains. That the fault lies in the muscles, whether the author's explanation of their function be strictly accurate or not, is shown by the results of treatment, for on their restoration by means of massage and electricity, the pains disappeared and the normal functions of the joint were restored. In some cases this treatment was supplemented with advan-

tage by a firm bandage around the joint, which served to restrict undue lateral movement.

The cases reported by the author furnish an additional argument as to the necessity of treating the muscles, even after the joint lesion has been cured, a measure that is often slighted under the belief that use will suffice to restore in a short time the tone and power of the atrophied muscles.

### THE CURABILITY OF CIRRHOSIS OF THE LIVER.

In a lecture delivered some time ago at the University of Naples, Professor Semmola called attention again to his method of treatment of cirrhosis of the liver, which he had first proposed in 1879 at the Amsterdam Congress, although he had suggested the possibility of curing the disease ten years before that time. The method is a very simple one, and consists in the enforcement of a pure milk diet, no solid food whatever being allowed. By this diet, he claims, nutrition is sustained, while the least possible work is put upon the digestive organs, and it is upon this physiological rest that he relies for a cure of the beginning cirrhosis. It is, of course, only in the earlier stages of the disease that a cure can be expected, that is, during the stage of interstitial hepatitis, before atrophy of the organ has advanced.

In this connection, the lecturer took occasion to inveigh against too great a devotion to pathology, which tended, he thought, to promote pessimism in therapeutics. At the post-mortem table interstitial hepatitis is generally found in its atrophic stage, when the newly-formed tissue has become fibrous and contracted, and when no hope of cure can be entertained. One who has such a picture always before his mind, as the interpretation of the early symptoms of the disease, is not encouraged to treat the affection to the end of effecting a cure.

Professor Semmola reported several cases in which the symptoms pointed to an early stage of hepatic cirrhosis, and in which a cure was obtained by means of a rigid adherence to a milk diet without solid food or drugs.

### URIC ACID AND GOUT.

At a recent meeting of the Medical and Chirurgical Society of London, a rather interesting discussion took place on the relation of the gouty diathesis to uric acid. Dr. Arnold Schetelig, of Hamburg, read a paper on the presence of free uric acid in the urine as a test of the existence of the gouty state. *Free* uric acid, he said, had a tendency to crystallize out and conglomerate with any other crystalline uric acid already present. Its quantity was determined by first ascertaining the total quantity of uric acid contained in a patient's urine, and then allowing an equal portion of urine to pass through a filter charged with uric acid, the "lithic filter." Free uric acid remained on the filter while the urates passed through unaffected. The author had analyzed the urine in fifty-five cases, and had found from twenty-five to fifty (and more) per cent. of the total uric acid to be in the uncombined crystalline form in the urine of patients who were either troubled with some form of true gout, or had been so previously. Dr. Schetelig suggested that this test might be used to distinguish between cases of genuine and spurious gout. This form of uric acid, he said, could by treatment with baths, or with alkaline waters, or both combined, be diminished for a while, but would in most cases reaccumulate.

The treatment of gout, considered in its relation to the excretion of uric acid, was the subject of a paper by Dr. A. Haig. The author considered especially the influence of phosphate of sodium on the excretion of uric acid. Pure phosphate of sodium, he said, had long been known to be a solvent of uric acid, and he had pointed out that it increased the excretion of that substance. All specimens of the salt, however, did not act equally well. Analysis of several specimens showed that a small percentage of sulphate of soda was generally present. When about fifteen per cent. of the latter salt was present the mixture did not cause increased excretion of uric acid, but caused marked pains in the joints, due probably to retention of uric acid in them. Also, if a little dilute phosphoric acid was mixed with the pure phosphate in solution, it then did not cause plus secretion of uric acid, but if a little bicarbonate of soda was mixed with it instead the plus secretion was well marked. The addition of a little bicarbonate of soda to each dose was therefore advised as likely to insure a sufficient excretion of uric acid. Dr. Haig thought the phosphate was not likely to be of use in acute gout because the acidity in this disease was high, but it appeared to be of considerable value in the mental depression of uric acid in which the acidity was low and falling.

### THE MURDERER'S GUILT AND THE SURGEON'S RESPONSIBILITY.

A legal decision of considerable interest to surgeons was rendered not long since in a murder trial in Liverpool. A man named Vaughan was tried for the murder of a Mr. Godfrey, whom he had struck on the back of the head with an adze, inflicting a scalp-wound behind the ear. The injured man was taken to a hospital, and there developed symptoms of compression of the brain. It was thought that the skull was fractured, and on consultation the surgeons determined to trephine. This was done, and the man died in consequence, apparently of hemorrhage from a large vessel opened during the operation. At the post-mortem examination it was found that there had been no fracture of the skull. At the trial the defence claimed that death resulted directly from the operation, and was not to be attributed to the original injury. The judge ruled, however, that this claim was inadmissible, as no culpable want of skill or negligence on the part of the surgeons could be proven.

Such questions have arisen before, and are liable to be raised in any case in which the murdered man does not die within a very short time after the injury has been inflicted. If the wounded man is saved by timely treatment the defence is very willing to profit by the surgeon's skill, though seldom ready to acknowledge its agency. But if treatment is unavailing in saving life, it is the surgeon, they say, and not the assailant who has killed the man. There is a precedent in the English courts for this ruling, which is cited by *The Lancet* in its comment upon the Liverpool case. Edward Lawless Pym was tried at Southampton, in the year 1846, for the murder of a Mr. Hawkey, and had the advantage of being defended by Mr. Cockburn (afterward Chief Justice of England).

Mr. Pym had shot Mr. Hawkey in a duel and wounded him. An operation was subsequently performed, and the wounded man died. Mr. Cockburn proposed to show that the operation performed was unnecessary, and that without it the patient might have lived. But the presiding judge, Mr. Justice Erle, after consulting with Baron Rolfe, laid it down as law that "where a wound is given which, in the opinion of competent medical advisers, is dangerous, and the treatment which they adopt is the immediate cause of death, the party who inflicted the wound is criminally responsible."

This ruling would seem to be a very just one, and moreover one that will ultimately be of benefit to the accused in similar cases. For the surgeon, assured that the death will not be laid to his door, can accept the responsibility of treatment with greater confidence, and the success of his efforts will not be jeopardized by nervous apprehension of failure.

## News of the Week.

TOKIO FEMALE HOSPITAL.—The Empress of Japan has always taken great interest in this institution, and lately made it a present of over $7,000.

A PHYSICIAN SIXTY YEARS OF AGE killed himself not long ago, in Paris, because he was unable to make enough from his practice to pay his rent. A very similar case occurred here not long ago, when an aged physician shot himself after vainly seeking death by poison.

POST-GRADUATE INSTRUCTION IN LONDON.—Charing-Cross Hospital, in London, gives a short post-graduate course; but this is said to be the only facility offered in that city for post-graduate instruction, and it is suggested that a school similar to those in New York, Vienna, and Berlin be established there.

A DICTIONARY OF MEDICAL SPECIALISTS is the title of a book that has lately appeared in London, which purports to give a complete list of all practitioners in London who devote themselves to any specialty. The work is edited by a lawyer.

WHERE AND WHO WAS THE DOG?—Our esteemed contemporary the Pittsburg *Medical Review* speaks in the following enigmatical manner concerning the last meeting of the American Medical Association: "The covert snarl of that mean beast, the Dog in the Manger, was perceptible to practised ears at the Newport meeting. It is a pity that this offensive canine must intrude at the Association meetings. He should be kept chained at home, or at least muzzled by his more judicious friends when allowed at large."

THE END OF COLLECTIVE INVESTIGATION IN ENGLAND.—The Collective Investigation Committee of the British Medical Association states in their report this year that the returns upon the subjects proposed for study have been so few that they think it best to discontinue the work entirely, and ask that the Committee be allowed to lapse at the end of its current year, in October. The editor of the *British Medical Journal* thus briefly and unsympathizingly announces its demise: "Its success has been so dubious, that after a brief period of existence its animation has, I regret to see, been suspended. I pointed out its sources of inherent weakness, and the improbability that it could fulfil the large expectations formed of it here, and which for a moment attracted the imagination of other associations and of the International Medical Congress. It was born with great *éclat*, baptized with many benedictions, welcomed with loud soundings of trumpet at Copenhagen; but neither energy, liberal subsidy, nor the devotion of some of the finest intellects in Europe could keep it alive."

THE MEDICAL PRACTICE LAW passed by the last legislature of Maine has been declared invalid. There was some technical defect in the law, which the next legislature will be asked to rectify.

THE AGENCY OF DISPENSARIES IN SPREADING CONTAGION.—To one who sees the often crowded waiting-room of any of the larger children's dispensaries of this city, the danger of the spread of contagious diseases through their agency seems no slight one, and they may not inaptly be called the clearing-houses for contagious disease. The existence of this evil has recently been brought to the notice of the authorities of Paris, and they have been requested to construct additional waiting-rooms for children suspected to be suffering from infectious diseases, and to delegate a medical officer to each dispensary for the purpose of making a selection of the cases, allowing only children recognized to be free from contagious disease access to the common waiting-room.

DR. ALEXANDER BROWN MOTT, of this city, died of pneumonia, in Yonkers, on August 12th. He was the son of Dr. Valentine Mott, and received his medical degree in 1850, after having studied a number of years in this country and in Europe.

The following minute was adopted by the Faculty of the Bellevue Hospital Medical College on August 15th:

"The Faculty of the Bellevue Hospital Medical College desire to record in their minutes an expression of deep sorrow at the death of their associate, the late Professor Alexander B. Mott. Professor Mott was one of the few remaining members of the original Faculty of the College. For twenty-eight years he had given his best efforts to the institution of which he was one of the founders; and many thousands of alumni can bear testimony to the value of his teaching. Endeared to his colleagues by long and intimate association, his death is felt by each one as the loss of an earnest teacher, a good and a true friend. AUSTIN FLINT, *Secretary*."

A SUMMER HEALTH-RESORT.—The name of the author of a paper with this title, published in the issue of August 3d, is Dr. Wm. H. Dukeman, and not Dakeman as printed.

SUNSTROKES IN NEW ORLEANS.—In the week ending July 23d, there were thirteen deaths from sunstroke in New Orleans, a very large number for that city, where deaths from this cause are much less frequent than during the heated spell in our northern climate.

DEATH OF DR. HILDRETH.—Dr. C. C. Hildreth, of Zanesville, O., died in that city on August 11th, of cerebral apoplexy. He was born in 1811, and had been in active medical practice for fifty-six years.

THE FIRST ANNUAL MEETING of the American Pædiatric Society, will be held in Washington, D. C., on September 20 and 21, 1889, under the presidency of Dr. A. Jacobi, of this city. The sessions will be held at the Army Museum Building, but one of the afternoon meetings will be held in the Johns Hopkins Hospital, Baltimore, Md., by invitation of the director of the hospital. The following papers are announced: Address by the President; "Notes on a Case of Ataxia in a Child of Ten Years," by A. D. Blackader, Montreal, Canada; "A Study of some of the Bacteria Found in the Dejecta of Infants Afflicted with Summer Diarrhœa" (second communication), by W. D. Booker, Baltimore, Md.; "Noisy Respiration," by Dillon Brown, New York; "Prolapsus Recti due to Large Stone in the Bladder in a Girl Three Years Old," "Two Cases of Nystagmus Associated with Choreatic Movements of the Head in Rachitic Babies," "Septic Diphtheria with Unusual Sequelæ," "Personal Prophylaxis in Diphtheria," by A. Caillé, New York; "Subcutaneous Emphysema in Children," "The Necessity of Prolonged Rest after Some Attacks of Diphtheria," "Two Cases of Carpo-pedal Contraction," by Charles Warrington Earle, Chicago, Ill.; "The Treatment of Scarlet Fever and its Complications," by J. Henry Fruitnight, New York; "Spurious Meningocele," "Double Empyema," by Francis Huber, New York; "Aneurism in Early Life," by A. Jacobi, New York; "A Contribution to the Summer Diarrhœas of Infancy," by John A. Jeffries, Boston (by invitation); "Tuberculosis of the Testis in Childhood," by H. Koplik, New York; "Cases of Spastic Paraplegia," by Thos. S. Latimer, Baltimore, Md.; "Scarlet Fever," by I. N. Love, St. Louis, Mo.; "The Artificial Feeding of Infants," by Arthur V. Meigs, Philadelphia, Pa.; "Case of Diaphragmatic Hernia, with Operation," "The Apparent Physical Contradiction Involved in the Reinflation of a Collapsed Lung while an Opening remains in the Pleural Sac," by J. O'Dwyer, New York; "A Case of Simple Muscular Atrophy of the Facio-scapulo-humeral Type," "Cerebral Sclerosis in Children," by Wm. Osler, Baltimore, Md.; "Diphtheria," by A. Seibert, New York; "Some Practical Points on the Diagnosis and Treatment of Malaria in Children," by H. N. Vineberg, New York; Titles not yet announced, W. T. Northrup, New York; J. L. Smith, New York; and V. W. Vaughan, Ann Arbor, Mich.

ANTIPYRINE AND LANOLINE have, it is stated, been adopted as official in the new edition of the Austrian pharmacopœia.

THE TERCENTENNIAL OF THE MICROSCOPE.—Preparations are already being made in several German university towns to celebrate next year the three hundredth anniversary of the invention of the microscope. Zacharias Janssen, of Magdeburg, is credited with having constructed the first microscope in 1590.

AN INTERNATIONAL CONGRESS OF DEAF-MUTES.—The first international congress of deaf-mutes was held in Paris on July 10 to 17, 1889. The subjects discussed were the relations of the deaf-mute to society, to labor, and to the laws of his country. There was also read an historical sketch of the benefactors of deaf-mutes from the time of the Abbé de l'Epée to the present. The congress also celebrated the centenary of the Abbé de l'Epée, who died in July, 1789, and erected a commemorative tablet upon the site of his birthplace at Versailles. The question of sign language was also discussed, and while most of the members agreed upon the necessity of teaching articulation, all were of the opinion that the sign language was of prime necessity as a medium of expression, and indispensable as an aid to the acquirement of knowledge and to the cultivation of the mental faculties.

THE DAILY NEWSPAPERS, at least, have cause to bless Brown-Séquard, for he has given them a very taking subject with which to while away the "silly season."

MARSHALL VOUGHT, for sixteen years warden of the almshouse on Blackwell's Island, died suddenly on August 13th, of heart failure.

ACTING ASSISTANT SURGEON MONTANYE, of the Marine Hospital Service, died in San Francisco on August 13th.

A USEFUL GIFT.—A citizen of Leipsic, possessed of ample means, and of the still rarer gift of knowing how to make them useful to his fellow-man, has just presented to the medical relief fund of that city and its neighborhood two extensive estates in the Saxon Erzgebirge, specially purchased by him as places to which the poor laborer or artisan, recovering from illness, may be sent for the completion of his cure. Both estates—the one near the Schneeberg, the other near the Schwarzenberg—are finely situated in a healthful, well-wooded, well-watered region, and have been pronounced, on the highest medical authority, to be admirably adapted for their purpose. The donor has made it a condition of his gift that his name be kept undivulged.—*The Lancet.*

THE LATEST NICKEL-IN-THE-SLOT MACHINE.—The latest in the way of development in automatic machines is one recently brought out in England, by means of which anyone can have his sight tested and receive an order for spectacles. The following is a description of the machine by a writer in the *Provincian Medical Journal.* There is the usual case, somewhat after the model of the weighing machine, but on the front face are two eye-holes, with depression underneath for the nose. You place a penny in the slot, press one foot on a pedal, look through the eye-holes, and by turning a small crank you bring a series of lenses into position. You are looking at a card, on which some words are printed, as, "If you can read this you do not require spectacles." If writing can only be read with certain lenses, then the number of spectacle required is also read, and on satisfying oneself that these lenses suit, on withdrawing the foot a box is set free, in which are order forms, on which the number can be entered. Convex and concave glasses are used for testing in this ingenious manner. The company offer to supply spectacles to order at 4s. 6d.

EAU DE COLOGNE TIPPLING.—It is said that the practice of drinking cologne is becoming very common both in Europe and in this country, and as an indication of this that the sale of the perfume has increased greatly of late years. Women are more addicted to the habit than men, and a writer in the *Quarterly Journal of Inebriety*, says that the presence of obscure and complex nervous disorders in a woman who uses cologne externally should always suggest the possibility of its internal use.

THE TENTH INTERNATIONAL MEDICAL CONGRESS.—The following notice has been received: We, the undersigned, do hereby give notice that, according to the resolution passed at the Washington meeting, September 9, 1887, the tenth International Medical Congress will be held in Berlin. The Congress will be opened on the 4th and closed on the 9th day of August, 1890. Detailed information as to the order of proceedings will be issued after the meeting of the delegates of the German Medical Faculties and Medical Societies at Heidelberg on the 17th of September in the current year. Meanwhile, we should feel sincerely obliged, if you would kindly make this communication known among your medical circles, and add in the same time our cordial invitation to the Congress. von Bergmann, Virchow, Waldeyer.

MME. DEJERINE KLUMPKE, an American wife of a Frenchman, has won the degree of "Doctoresse" from the Paris Faculty of Medicine, with high honors. The subject of her thesis was: "A Contribution to the Study of Polyneuritis in General, and of Lead Paralysis and Atrophy in Particular."

THE KOLA-NUT.—The value of the kola-nut (seeds of Sterculia acuminata) as a dietetic and therapeutic agent has been recently tested by Surgeon R. H. Firth. These nuts are allied in composition to cocoa, coffee, and tea, but contain a relatively large amount of caffeine. The properties ordinarily assigned to kola are those of a strong tonic and stimulant to the nervous system, counteracting and removing the sense of exhaustion after fasting and fatigue; it has also been credited with having an antagonistic action to alcohol, and it has been said to purify water. From his observations Surgeon Firth concludes that kola is in no sense a food; that it increases the total urinary water, with a slight reduction of its total solids, and a marked reduction of the extractive; that it has a peculiar stimulant action on the nervous system, temporarily strengthens the heart-beat, and increases the arterial tension. In times of exertion and fasting it wards off the sense of mental and physical depression and exhaustion. As a therapeutic agent in convalescence, and as an antagonist to alcoholic sequelæ, kola has not yielded any positive results in Surgeon Firth's hands. For the purification of water it does not appear to be superior to other mucilaginous seeds, its action being purely mechanical. In this report due prominence is given to the importance of separating seeds which contain no caffeine, such as Garcina kola and Sterculia cordifolia, as these would speedily discredit the employment of kola by the troops under conditions when it might possibly be of service. It appears that an infusion, from its astringent action, might be used for those suffering from diarrhœa.—*Lancet.*

THE TREATMENT OF ACUTE RHEUMATISM.—Dr. W. N. Maccall read a paper upon this subject at the Clinical Society of Manchester. After reviewing the previous treatment of acute rheumatism during the last twenty-five years, Dr. Maccall considered the value of the present routine treatment by salicylic acid and its allies or derivatives under the following headings: 1. In relieving pain and lessening fever in acute rheumatism, the salicyl treatment is undoubtedly the most effective we know of. 2. The salicylates do not preuent the rare complication of hyperpyrexia, and are absolutely useless in its treatment. 3. It is doubtful if they prevent endocardial or pericardial troubles, the percentage remaining about the same (fifty per cent.) since the salicyl treatment as before. They seem to have no influence in curing these troubles when they do occur. 4. There is no proof that the salicylates prevent relapse. 5. It is not proved that the salicylates lessen the duration of the disease, or that they prevent anæmia. With regard to the particular form of the remedy, most writers recommend (and Dr. Maccall agrees with them) salicylate of soda in twenty-grain doses, at first every hour, for three or four hours, according to circumstances. It should be continued in diminishing doses for at least eight or ten days after all pain and pyrexia have gone, and in most cases should be followed by iron. Salicylic acid, salicin, and salol might be tried in exceptional cases where the soda salt was not well borne. In young children antipyrin might be substituted with advantage. In convalescence, Sir A. Garrod's alkaline mixture, followed by iron, was advised; and, if any joint remained stiff or swollen, blistering or painting with iodine was useful. Dr. Braddon expressed himself as disappointed with the salicylate treatment, and preferred, as a rule, the alkaline combined with Dover's powder. Dr. Railton considered salicylic acid or its salts to be comparatively useless in acute rheumatism, except as regards the relief of pain.

A RESPIRATION CHAIR.—In a graduation thesis Dr. Carl Grunert, of Halle, discusses and describes the treatment of emphysema and asthma by means of the respiration chair. The chair is so constructed as to effect by means of levers and bands attached to it pressure and traction on the thorax similar to that exerted by the muscles in forced respiration. A cuirass makes backward and downward pressure on the thorax, while a broad band compresses the abdomen and so increases the intra-abdominal pressure; the abdominal viscera then force the diaphragm upward, and the latter rises. The ultimate effect, according to the author, is to make a forced expiration possible, to considerably decrease the volume of the thorax, and to empty more completely the hitherto badly aerated alveoli, so that at the next inspiration more oxygen enters; any bronchitic mucus which may be occluding the alveolus is also expelled. This is followed, of course, very soon by diminution of the dyspnœa. The disturbance of the circulation of the blood in consequence of emphysema is recognized by the abnormal loudness of the second pulmonary sound. This was found to decrease in three patients after a treatment of from three to six weeks in the respiration chair, while the first mitral sound increased, showing that the cardiac muscle had become stronger. Emphysematous patients treated in the chair lost more or less completely their chronic bronchial catarrh; the attacks of coughing improved greatly, permitting sleep to be obtained without disturbance; the asthmatic symptoms, too, were frequently cured. A number of cases treated by this method in the chair are described, and the results obtained tend to show that in many instances the respiration chair may prove an advantageous method of treatment.

"ZYMOTIC DISEASES, CONSIDERED WITH REFERENCE TO THEIR CAUSE, EXTENT, AND PREVENTION," is the title of an interesting and instructive pamphlet recently published by Dr. R. French Stone, of Indianapolis.

THE SCOTCH MEDICAL SCHOOLS.—A proposition was made recently in the House of Lords to abolish the medical faculties in the Scotch universities. As might be expected, it met with but little favor in or out of Parliament.

## Reviews and Notices of Books.

A COMPENDIUM OF DENTISTRY. By JULIUS PARREIDT, Dental Surgeon at the Leipsic Surgical Polyclinic. Translated by LOUIS OTTOFY, Chicago; with Notes and Additions by G. V. BLACK, M.D., D.D.S., Chicago. 8vo, pp. 229. Chicago: W. T. Keener. 1889.

ACCORDING to the author's preface, the family medical adviser should always be acquainted with a few facts concerning dentistry. He should know the indications for filling teeth. He should be able to trace the possible connection between diseased teeth and neuralgia, and other nervous disorders, meningitis, pyæmia, attendant on inflammation of the jaws, etc. All of this information he can obtain from this volume, which is, however, intended for students of dentistry rather than of medicine. It would be a useful book of reference for the library of a general surgeon. An attractive typography, numerous and well-executed illustrations, together with creditable work on the part of the translator, combine to make an attractive volume.

HANDBOOK OF SKIN DISEASES. By ARTHUR VAN HARLINGEN, Professor of Diseases of the Skin in the Philadelphia Polyclinic. Second edition. 12mo, pp. 410. Philadelphia: P. Blakiston, Son & Co. 1889.

AFTER a brief summary of the primary lesions of the skin (macules, papules, etc.), with a table of classification, follow in alphabetical order (titles in bold-faced type) the various skin diseases, remedies, etc. Under each title pathology is briefly considered, while diagnosis and treatment are given at greater length. Cutler's "Manual of Differential Diagnosis" is largely drawn upon for the former. Naturally, in the various descriptions occurs the impress of his own views. In a foot-note under "Acne" the author denies that masturbation is a cause thereof, and strongly deprecates the use of cold sounds as a curative agent, and hopes "that this cynical procedure will rarely be employed;" the colored plates and woodcuts are better executed than is usually the case in works of this class. The manual is interesting as the exponent of the views of a writer of reputation and ability, and students will find it remarkably well adapted to preparing them for their examinations.

MATERIA MEDICA, PHARMACY, AND THERAPEUTICS. By CUTHBERT BOWEN, M.D. 12mo, pp. 366. Philadelphia: F. A. Davis. 1889.

THIS belongs to the Physicians' Ready Reference Series. It consists of a compilation from lecture-room notes, and the various text-books on the above topics. It is managed in the form of questions and answers, and according to our conviction, may be useful to Philadelphia medical students, but certainly to no one else.

ELECTRICITY IN THE DISEASES OF WOMEN. By G. BETTON MASSEY, M.D., Physician to the Nervous Department of Howard Hospital, Philadelphia, etc. 12mo, pp. 210. Philadelphia and London: F. A. Davis. 1889.

THE present discussion on the general topic of gynæcological electro-therapeutics gives much interest to this systematic presentation of ideas. After a description of the apparatus required in galvanism, follows an interesting chapter on the action of concentrated milliampère currents on organized tissues. Throughout the book special reference is made to the action of concentrated currents. The physiological effects of Faradism and Franklinism are in turn discussed, together with the operative details of pelvic electro-puncture and intra-uterine galvano-chemical cauterization. Then succeed chapters on the application of the proper current to the various gynæcological maladies. So much for the general outline of the work. The writer believes that gynæcological electro-therapeutics are due to a "dawning reaction from the ultra-mechanical methods of the followers of the late Marion Sims." He is right in saying that an acquaintance with physics is essential to a proper conception of what electricity can do in pelvic diseases, and of how it should be used. In regard to the greatest mooted point of the present day—the Apostoli theory of curing uterine fibroids, the writer expresses himself somewhat cautiously. We quote (p. 123): "Diminishing bulk, checking hemorrhage, easy menstrual periods, relief of pressure symptoms, and general restoration of the patient has been the usual result in all cases so far operated upon by the author; and this is invariably the verdict of all those who have used currents intelligently for this condition." Dr. Massey believes that the lessening of bulk of fibroids may be due, not only to the denutritive and atrophic action of the current on fibroid tissue, but also to its contractile influence on the muscular tissue of the uterus and on the true myomatous tissue of the growth itself. We can heartily recommend the book as an epitome of the most recent views on this topic.

A DIALOGUE AGAINST THE FEVER PESTILENCE. By WILLIAM BULLEIN. From the edition of 1578, collated with the earlier editions of 1564 and 1573. Edited by MARK W. BULLEN and A. H. BULLEN. Part I. The Text. London: Published for the Early English Text Society by N. Trübner & Co. 1888.

THIS book was a popular one some three hundred years ago, being full of alleged "merrie tales," and divers archaic disquisitions upon men, mortality, and the pestilence.

THE ANATOMIE OF THE BODIE OF MAN. By THOMAS VICARY, Sergeant of the Surgeons to Henry VIII., etc. Surgeon to St. Bartholomew's Hospital, London, 1548–62. The edition of 1548, as re-issued by the Surgeons of St. Bartholomew's in 1577. With a Life of Vicary, Notes on Surgeons in England, Bartholomew's Hospital, and London in Tudor Times. An Appendix of Documents and Illustrations. Edited by FREDERICK J. FURNIVALL, M.A., HONORABLE DR. PHILIP and PERCY FURNIVALL. A student of St. Bartholomew's. Part I. EARLY ENGLISH TEXT SOCIETY. Extra Series, LIII. London: N. Trübner & Co. 1888.

VICARY'S Anatomy was the first English work on the subject, and it was, with various supplements, the standard text-book for one hundred and fifty years. The republication of so historic a work will gratify many physicians interested in the development of anatomical science. The book will interest all who are fond of the quaint and curious in literature.

TRANSACTIONS OF THE THIRTY-FIFTH ANNUAL SESSION OF THE MEDICAL SOCIETY OF NORTH CAROLINA (for the year 1888). 8vo, pp. 252. Edited by the PUBLICATION COMMITTEE. Wilmington. 1888.

ONE of the most interesting chapters of this creditable volume relates to the doings of the State Board of Examiners. They are working faithfully and practically. We believe, by the way, that our Southern friends were the pioneers in this direction.

REPORT OF THE CONNECTICUT STATE BOARD OF HEALTH FOR THE YEAR 1888. 8vo, pp. 199. New Haven: Tuttle, Morehouse & Taylor. 1889.

AN attractive volume, full of vital statistics. Papers on water pollution and State hygiene.

THE STUDENT'S TEXT-BOOK OF PRACTICE OF MEDICINE. By ANGEL MONEY, M.D., London, Assistant Physician University College Hospital, London. 12mo, pp. 444. H. K. Lewis. 1889.

THIS is a remarkably well-written, comprehensive, and concise epitome of the practice of medicine, and is well calculated to meet the needs of the student who is attending lectures or preparing for the various examinations.

AMERICAN RESORTS, WITH NOTES UPON THEIR CLIMATE. By BUSHROD W. JAMES, A.M., M.D., Member American Association for the Advancement of Science, etc. 8vo, pp. 285. Philadelphia and London: F. A. Davis. 1889.

THE reader will be somewhat disappointed in the perusal of this work, as it does not cover the intended ground, and is entirely too superficial in the treatment of the subject. The general idea is a good one, as it is free from any appearance of advertising watering-places or other health-resorts; but, scientifically speaking, it is little more than a general railroad guide to different parts of our continent, with an incidental reference to the character of the climate in different sections. The foundation is laid broadly enough, but useful details are almost everywhere wanting. There is an excellent official railroad map of the United States, which gives the work its chief value.

THE ESSENTIALS OF PHYSICAL DIAGNOSIS OF THE CHEST AND ABDOMEN. By I. WALLACE ANDERSON, M.D., Physician to the Royal Infirmary, Glasgow. 12mo, pp. 152. New York: Macmillan & Co. 1889.

THIS little work maintains its claim to recognition as one of many of its kind, and proves the author to be an exact and careful teacher.

THE OLD HOSPITAL AND OTHER PAPERS. By D. B. ST. JOHN ROOSA, M.D., LL.D. 8vo, pp. 320. New York: William Wood & Co. 1889.

"THE central idea of the papers in this volume," says the author, "is an attempt to define and adjust the relations of the medical profession to the community which it serves." The author has succeeded exceedingly well in his attempt to do this. Although an enlarged edition of the author's former work, "A Doctor's Suggestions to the Community," it appears almost as an essentially new work, not only as regards its elegant typographical execution, but as to interesting material which has been added. The description of the old New York Hospital is the first article, and is written in the author's best style. To read it is to have been there and lived there. The other sketches have also merits of their own—all interesting, practical, suggestive, and charmingly written. The author has the happy faculty of riveting an argument by an apt illustration, thus not only making it more impressive, but if possible more convincing. Essentially broad in his grasp, he takes high ground and opens up large views of the situation and prospect. Aside from its sound doctrine, the work will be read for its intrinsic literary merit, and this will be one of its strong holds with the lay public. Without wishing to make invidious distinctions, we confess to partiality for "the coming medical man," "the relations of the medical profession to the State," and "the means of effecting the unity of the medical profession"—all well written and sound. But what shall we say of the sketch of Little? We all loved Little, and so did the author.

The makeup of the book is a marvel of the printer's art.

KIRKES' HANDBOOK OF PHYSIOLOGY. By W. MORRAND BAKER, F.R.C.S., Surgeon to St. Bartholomew's Hospital, etc., and VINCENT DORMER HARRIS, M.D., London, Fellow of Royal College of Physicians, etc. Twelfth edition. 8vo, pp. 757. New York: William Wood & Co. 1889.

THE present edition of this admirable text-book has been rearranged, revised, and rewritten, and is at present fully up to the times in its treatment of the subjects which are the leading ones in the study of physiology. Many important additions have been made in the chapters on blood, heart, and muscular system, while the articles on the reproductive organs and the nervous system have been to a great extent rewritten. The necessity for the latter was quite apparent, considering the advances made in that department of study even within the last few months. The illustrations are accurate and numerous, and add very much to the intrinsic value of the work. Altogether it is one of the best text-books on the subject for the use of teachers and students.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. vi. Edited by J. EWING MEARS, M.D., Recorder of the Association. 8vo, pp. 568. Philadelphia: P. Blakiston, Son & Co. 1888.

THIS is an unusually interesting volume, and is full of well-written and practical papers on surgical subjects. The proof of this is indicated by the following list: "Relation of Social Life to Surgical Disease," by D. Hayes Agnew; "Study of Excision of Larger Joints," by John Ashhurst, Jr., M.D.; "Relation of Micro-organisms to Injuries and Surgical Diseases," by N. Senn, M.D.; "Three Successful Cases of Cerebral Surgery," by W. W. Keen, M.D.; "The Formation of an Artificial Urethra in Prostatic Obstructions," by Hunter McGuire, M.D.; "The Operations of Supra-pubic Lithotomy, and the Surgical Management of Typhlitis and Perityphlitis," by W. T. Bull, M.D.; "Surgical Interference in Perforating Typhoid Ulcer," by J. Ewing Mears, M.D.; "Ligation of Carotid and Subclavian Arteries for Innominate Aneurism," by John H. Packard, M.D.; "Tracheotomy and Intubation in Croup," by George W. Gay; "Pregnancy and Operative Surgery," by Louis McLane Tiffany, M.D.; "Nerve Stretching," by N. P. Dandridge, M.D.; "Nephrectomies for Gunshot Wounds of Kidney," etc., by DeForest Willard; "Shock," by David W. Cheever, M.D.; "Experiments with Pyogenic Bacteria," by Roswell Park; "Cyst of Pancreas Successfully Removed," by W. S. Tremaine, M.D.; and "Pelvic and Abdominal Drainage," by David Prince, M.D.

TRANSACTIONS OF THE ROYAL ACADEMY OF MEDICINE IN IRELAND. Edited by WILLIAM THOMPSON, M.A., F.R.C.S., General Secretary. 8vo, pp. 472. Dublin: Fannin & Co. 1888.

THE volume is one of the most interesting of the series, is full of practical papers on different branches of medicine and surgery, and is plentifully supplied with beautiful plates. Altogether it is a model of its kind, and well sustains the reputation of this Academy for accurate and solid work.

MERCK'S INDEX. A catalogue of the various products of the celebrated Darmstadt firm. Useful for reference.

MEDIASTINAL DISEASE. By HOBART AMORY HARE, M.D., Demonstrator of Therapeutics, University of Pennsylvania, etc. 8vo, pp. 150. Philadelphia: P. Blakiston, Son & Co. 1889.

THIS essay gained for its author the Fothergillian Medal of the London Medical Society in March of last year. Dr. Hare deserves great praise for writing upon a subject of which very little systematic knowledge has hitherto been had. No attempt has been made to touch upon mediastinal disease affecting well-defined organs in this part. Chapters are included on mediastinal tumors (cancer and sarcoma, lymphoma, lymphadenoma, and fibroma), inflammations, abscess, hæmatoma, cysts (dermoid and hydatid). In all, the records of five hundred and twenty cases have been investigated and collated in these pages. In these latter days, when everyone rushes into print with hasty reports of cases, it is a pleasure to observe the care with which the present volume has been prepared. Of this kind of literary medical work we cannot have too much. The present instance reflects great credit alike upon the writer and American literature.

THE LIFE INSURANCE EXAMINER: A Practical Treatise upon Medical Examinations for Life Insurance. By CHARLES F. STILLMAN, M.S., M.D., Medical Examiner for the Mutual Life Insurance Company for the General Agency of the City of New York; Examining Surgeon of the Travelers' Insurance Company of Hartford, Conn., for the City of New York; Clinical Professor of Orthopædic Surgery in the Woman's Medical College of the New York Infirmary; Orthopædic Surgeon to the New York Infant Asylum; Member of the American Orthopædic Association; Permanent Member of the American Medical Association; Fellow of the New York Academy of Medicine; Member of the New York Medico-legal Society, and of the New York County Medical Society. New York and Chicago: The Spectator Company. 1888.

A NEW field of activity for the physician, we might almost say a new profession, has arisen within the past few years in connection with life insurance. The examination of an applicant for insurance is no longer the perfunctory performance it was a few years ago, but is a thorough investigation of the physical condition of the person who seeks insurance on his life. And in proportion as the examination has become a more searching one, has its importance increased, until now the position of medical examiner to a life insurance company is one of great responsibility and trust. As an evidence of the growing dignity of this branch of the profession, may be mentioned the fact that the University of Vermont has added to its courses of lectures one on life insurance examinations, the first occupant of this chair being the author of the work before us. The book is notable for its practical character, the aim of the author having been to provide the medical examiner with a reliable guide which will point out to him clearly what he is to do, and what not to do, when an applicant comes to him for examination. The first part deals with life insurance formalities, giving the reader an idea of the forms used by different companies, with the questions put to the applicant. In the second part directions are given for the examination of the applicant; and the third part is devoted to a consideration of the diseases relating to life insurance. An appendix contains some statistical tables, instructions to agents, and an abstract of a paper by Mr. John M. Taylor on some legal questions as to the office and evidence of the medical examiner. The bibliography of life insurance examination is very meagre, and the author had almost a virgin soil to work upon, but he has tilled it so well and so thoroughly that he has left nothing to be desired. Some of the instructions are rather elementary, but that can scarcely be called a fault, and those who do not need them will overlook their presence for the sake of the others, few we hope, to whom they may be a help. The book is one which should be in the hands of every life insurance examiner; and indeed, we know of one large company, at least, which has presented a copy to each of its examiners, an example which other companies would lose nothing in following.

ELECTRO-THERAPEUTICS; OR, ELECTRICITY IN ITS RELATIONS TO MEDICINE AND SURGERY. By WILLIAM HARVEY KING, M.D. New York: A. L. Chatterton & Co.

THIS work is one of a number of similar text-books which have been published for the instruction of students since electricity has come to be recognized as one of our most active therapeutic agents. It has nothing special to give it a higher claim to recognition than its predecessors.

THE DIAGNOSIS AND TREATMENT OF EXTRA-UTERINE PREGNANCY. By JOHN STRAHAN, M.D., M.Ch., M.A.O. Pp. 134. Philadelphia: P. Blakiston, Son & Co. 1889.

THIS essay is the first to receive the William F. Jenks memorial prize, given by the College of Physicians of Philadelphia. It is an excellent review and criticism of the work done in this difficult branch of obstetrics up to the present time. The writer has been thorough and conscientious in his researches, careful in his statements, and methodical in his manner of presentation. All physicians who are likely to encounter cases of extra-uterine pregnancy should certainly read carefully this monograph. It will be a great assistance in the midst of the distracting perplexity which surrounds such a case.

PSYCHOLOGY AS A NATURAL SCIENCE APPLIED TO THE SOLUTION OF OCCULT PSYCHIC PHENOMENA. By C. G. RANE, M.D. Pp. 541. Philadelphia: Porter & Coates. 1889.

THIS is a work which the busy practitioner will have no time for. The author bases his psychology on the work of Dr. Friedrich Eduard Beneke, and endeavors to explain psychological phenomena in a non-materialistic manner. He thinks he has proven the possibility of an intercourse between departed spirits and this corporeal world.

PHYSIOLOGICAL NOTES ON PRIMARY EDUCATION AND THE STUDY OF LANGUAGE. By MARY PUTNAM-JACOBI, M.D. Pp. 120. New York: G. P. Putnam's Sons. 1889.

THIS volume contains the two essays published several years ago in the *Popular Science Monthly*, entitled "An Experiment in Primary Education," as well as an essay on the "Flower or the Leaf," and one on "The Place for the Study of Language." Space is lacking for a detailed analysis of these interesting and suggestive papers, which deal with some of the most perplexing subjects of pedagogics. The whole value of the methods employed in the "Experiment in Primary Education," could not be estimated until the child had reached adult life, and was placed in comparison with those whose education had been formed in another mould. Moreover, to test such a system a number of children, with their different minds, would have to be put through the same process. The aim of Dr. Putnam-Jacobi is admirable and one worthy of high consideration, that of imbuing a child early with a scientific method. There is no doubt that much is lost for the child in permitting it to waste its brain-force on trifling, unimportant things which will never be of the slightest use to it, when it might have been amused and instructed at the same time with the fundamental truths of nature.

PROCEEDINGS OF THE CONNECTICUT MEDICAL SOCIETY FOR 1888. 8vo, pp. 240. Edited by N. E. WORDEN, M.D., Secretary. Hartford: Case, Lockwood & Brainerd Co. 1888.

THIS Society is nearing its centennial, having been established in 1791. The present records are up to its high standard in the past, and contain many papers of interest.

INTERNATIONAL POCKET MEDICAL FORMULARY: With an Appendix Containing Posological Table: Formulæ for Inhalations, Suppositories, Nasal Douches, Eye Washes, and Gargles; Hypodermic Formulæ; Table of Hypodermic Medication; Use of Thermometer in Disease; Poisons and their Antidotes; Post-mortem and Medico-legal Examinations; Artificial Respiration; Ligation of Arteries; Obstetrical Table; Urinalysis; Differential Diagnosis of Eruptive, Typhoid, and Typhus Fevers; Tables of Pulse, Temperature, Respiration, Motor Points, etc. By C. SUMNER WITHERSTINE, M.S., M.D., Associate Editor "Annual of the Universal Medical Sciences;" late House Surgeon Charity Hospital, New York; Visiting Physician Home for the Aged (Little Sisters of the Poor), Germantown, Philadelphia. London and Philadelphia: F. A. Davis. 1888.

WE regret that we cannot praise this work as much as we can the diligent research made by the compiler in collecting so many formulæ, and the good taste of the

publisher in getting up the book in such a convenient and tasteful shape. We do not like the book because we do not approve of ready-made prescriptions, for the physician who does not know enough of the action of remedies and of the art of prescribing to enable him to devise his own formulæ as they may be required, ought to seek some other employment. Unfortunately, however, there are medical practitioners of this kind, and to these we can recommend the work most highly. If they will consult it frequently, and always when they feel called upon to order any medicine, they will in most cases do no harm to their patients, and may occasionally be able to benefit them. The diseases are arranged alphabetically, and under each are given the different formulæ which have been recommended at one time or another by various authorities. The book is interleaved so that the owner can add such formulæ as he may find in the course of his reading.

THE YEAR BOOK OF TREATMENT FOR 1889: Being a Critical Review of the Practice of Medicine and Surgery during 1888. Philadelphia: Lea Brothers & Co. 1889.

THERE is a great deal of useful knowledge contained within the covers of this little book, and though an attentive reader of any good medical journal will find little here that he has not seen mentioned in his journal, he will find it systematically arranged and convenient for reference. It is impossible, of course, to review and abstract everything that has been published during the year, and the reader would be disappointed if he expected to find everything he wanted in this book; but of all the year books, large or small, none is better than this, and none contains so much that is useful in so compact a form.

INTESTINAL SURGERY. By N. SENN, M.D., Ph.D., Attending Surgeon to Milwaukee Hospital, Professor of the Principles of Surgery and Surgical Pathology, Rush Medical College, Chicago, Ill. Pp. 257. Chicago: W. T. Keener. 1889.

IN this branch of surgery, which, from its intrinsic interest and great importance, has taken so prominent a place in science, Dr. Senn is a pioneer, and no greater authority is there than he. He has devised several ingenious operations, one of which, intestinal anastomosis by perforated decalcified bone plates, would in itself win him fame. His new work, consequently, is both valuable and welcome. It consists of three papers, which have been read before medical associations and have appeared in various journals, hence any exhaustive review is unnecessary. The first is "The Surgical Treatment of Intestinal Obstruction." It is very thorough, treating exhaustively irrigation of the stomach, distention of the colon with fluids, rectal insufflation of gas, tubage of colon, taxis, massage, puncture, compression, enterotomy, colotomy, and abdominal section. The latter subject is perhaps the most valuable, as it details his methods of intestinal anastomosis, especially that with the use of bone-plates or catgut rings. The second paper gives the results of years of experiments in intestinal surgery on men and animals, with special reference to obstruction. A more interesting paper would be hard to find, and the conclusions drawn are of inestimable value. That comparatively new operation, omental grafting and omental transplantation, is discussed and detailed. The third and last paper, which was read before the American Medical Association in 1888, is entitled "Rectal Insufflation of Hydrogen Gas an Infallible Test in the Diagnosis of Visceral Injury of the Gastro-intestinal Canal in Penetrating Wounds of the Abdomen." He maintains that the alimentary canal is permeable to insufflation, either by the mouth or anus, but especially by the latter; that it is a safe operation, and is a sure means of diagnosis. All in all, the work can be criticised only to praise.

EXPERIMENTAL SURGERY. By NICHOLAS SENN, M.D., Ph.D., Attending Surgeon to the Milwaukee Hospital; Professor of the Principles of Surgery and Surgical Pathology in Rush Medical College, Chicago. Pp. 522. Chicago: W. T. Keener. 1889.

IN writing this work Professor Senn, who is recognized as one of the leading and most original surgeons of the day, has again made debtors of the profession and the public. For a number of years he has been carrying on experimental work, and this book is a clear, beautifully written, and intensely interesting account of these experiments, with their results. He first takes up that thorn of every surgeon's flesh, intra-capsular fracture of the neck of the femur. He shows theoretically and by experiment that bony union may not only be hoped for, but that nothing short of bony union of the fragments should satisfy the surgeon. If the fracture is impacted, manipulate as little as possible and fix by a plaster bandage on the body and both legs. If unimpacted, he puts on the plaster and obtains lateral pressure by an ingenious screw, the frame of which is worked into the plaster during application. A sure method, and the one to be adopted if the patient is in good condition, is to nail the fragments together with aseptic steel, ivory, or bone nails. The subject of intra-capsular fracture is most exhaustively treated, and an admirable résumé of the literature of the subject is given. He next discusses the ligature of blood-vessels, and in this day, when there is so much difference of opinion on the subject, the work is most timely. The method of cicatrization is thoroughly studied—in short it is a complete work on ligatures, interesting and valuable alike to both student and practitioner. The conclusions drawn are about as follows: That the aseptic catgut ligature is the safest and most reliable agent in securing either provisional or definitive closure of blood-vessels; the thrombus formed does not organize and takes no active part in the obliteration which results from connective tissue and endothelial proliferation; in ligation, the sheath of the vessel can be safely opened freely; in ligating large arteries in their continuity near a collateral branch, the double aseptic catgut ligature is preferable to the single ligature, and should be used in tying varicose veins. Air embolism, the result usually of the entrance of air into the veins during operation at the neck, is next studied both experimentally and clinically. It is shown that the chief cause of death in such a condition is mechanical overdistention of the right ventricle of the heart, and asphyxia from obstruction to the pulmonary circulation consequent upon embolism of the pulmonary artery. The latter is relieved if the heart is kept acting long enough to drive the air into the systemic circulation. The operative treatment, after stimulation, etc., consists of aspiration of the right ventricle, or, if the air entered through the internal jugular, catheterization of the right auricle through the vein. By these means, the air and spumous blood are removed, and very often the patient could be saved. The doctor makes an admirable and able argument in favor of this treatment. A hundred pages or more are devoted to the surgery of the pancreas. The literature on the subject is very scanty, and found only in medical journals. This is the first attempt to put it together and present it in a systematic form. Besides being a résumé of the literature of the subject, the article contains the results of the author's own researches, and most valuable they are: wounds, gangrene, abscess, hemorrhage, cysts, tumors, etc., are all thoroughly treated. The remainder of this most excellent work is made up of two papers: First, "An Experimental Contribution to Intestinal Obstruction," read in the Surgical Section of the Ninth International Medical Congress; second, "Rectal Insufflation of Hydrogen Gas an Infallible Test in the Diagnosis of Visceral Injury of the Gastro-intestinal Canal in Penetrating Wounds of the Abdomen." Both of these articles are presented in his new work on intestinal surgery which is reviewed below.

# Society Reports.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, April* 10, 1889.

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

### REPORT OF THE COMMITTEE ON MICROSCOPY.

EXAMINATION of the specimen referred to the Committee by Dr. S. J. McNutt, at the meeting of March 27th, shows it to be the newly formed membrane of pachymeningitis interna hæmorrhagica. No lesion in the substance of the brain was apparent. Respectfully submitted, JOHN S. ELY, IRA VAN GIESON.

DR. H. P. LOOMIS presented a specimen of

### MEDULLARY CANCER OF THE KIDNEY.

The tumor was removed from the body of a woman, twenty-eight years of age, who died in Bellevue Hospital. The principal complaint was of intense pain in the left side. At the autopsy the left kidney was found greatly enlarged, and on section the tumor was found to be a medullary cancer. It consisted of a thick, grumous material, and scarcely any true kidney tissue was found. The condition was rather a rare one in the speaker's experience.

Dr. Loomis also presented a specimen of

### CHRONIC DIFFUSE NEPHRITIS, WITH CONTRACTED KIDNEY, IN A CHILD ELEVEN YEARS OLD.

"The patient was a girl, eleven years of age, the second of four children. The eldest is now sixteen, and the youngest died in infancy of hydrocephalus. Her father contracted syphilis one year before the birth of his first child, and died when the patient was six years of age, having been an invalid for a number of years. Her mother has always been well. There is no history of gout in either parent's family. Her mother's family is rheumatic, and her father's phthisical. The patient was of feeble physique, but had never been severely ill, except with whooping-cough and chicken-pox.

"The first symptoms of renal disease developed about a year before her death. Albumin and casts were constantly found in the urine during the last eight months of life, and there was gradually developed marked left ventricular hypertrophy. The other usual symptoms of chronic diffuse nephritis were well marked. The direct cause of death was lobular pneumonia, attended by suppression of urine and uræmic symptoms.

"*Autopsy*, made fifteen hours after death.—Body emaciated; some œdema of the ankles; slight puffiness under the eyes.

"Heart: the wall of the left ventricle was one inch in thickness, the cavity was not dilated, and there was no valvular lesion.

"Lungs: there were the characteristic appearances in both lungs of lobular pneumonia. The liver and spleen presented a normal appearance.

"The kidneys were about one-third their normal size; capsule thickened and adherent; surface granular; color pale; cortex diminished in a few places; markings generally absent. A microscopical examination showed the following changes: An obliterating endarteritis of almost all the smaller arteries; the external coat of the arteries was also thickened; there was a large amount of connective tissue increase not only around the tufts and between the tubes, but also in dense patches throughout the cortex. Many of the glomeruli had the appearance of having undergone amyloid change, but the gentian-violet test showed that the material was not waxy. The tubes showed granular fatty degeneration.

"About a year ago the patient's older sister, without any apparent cause, developed all the symptoms of Bright's disease, and has been growing steadily worse ever since, following a similar course to her sister. To-day she has œdema under her eyelids, hypertrophy of the left ventricle, complains of severe headache, and is often so drowsy that she can with difficulty be aroused. Albumin and casts appear in the urine at times.

"In reviewing the history of these two cases the only conclusion which I can come to is, that the syphilitic taint inherited from the father showed itself in the children by the development in the kidney of the changes which are characteristic of such a condition.

"Neither of the children had had scarlet fever, nor were there any signs of renal disease until they reached in the one case the age of ten, and in the other the age of fifteen years. This seems to bear out the statistics of Fournier of 212 cases of hereditary syphilis, in which he found the symptoms of the inherited infection showed themselves in the maximum number of cases about the twelfth year.

"The kidneys were well-marked specimens of contracted kidneys, such changes are rarely met with excepting in a gouty or syphilitic diathesis. I find the records of such changes in children are exceedingly rare even in the offspring of gouty and syphilitic parents. Ziegler in his work on Pathological Anatomy says that in congenital syphilis induration and contraction of the kidneys have in somewhat rare instances been observed. Possibly these kidneys would come under this category. Certainly neither child presented any other evidence of hereditary syphilis.

"In looking up the literature of the subject I find that Foster, in 'Jahrbuch für Kinderheilkunde,' describes two almost identical cases of contracted kidneys in children—a boy and a girl, aged respectively four and a half and nine and a fourth years—the offsprings of a syphilitic father. The kidneys were small, and with adherent capsules. There was also left ventricular hypertrophy. These cases had also been referred to by Dr. Delafield in his last article on Bright's disease."

DR. S. T. ARMSTRONG presented the following specimens:

### HYPERTROPHY OF THE TUNICA VAGINALIS IN A CASE OF HYDROCELE.

W. P——, aged twenty, a native of France, a negro, was admitted to the hospital February 14, 1888. He had had gonorrhœa the previous month, with subsequent hydrocele. On the date of admission he was tapped, 200 c.c. of fluid being removed. (The fluid was used for bacteriological purposes.) On February 22d he was tapped, and tincture of iodine was injected, and one week later he was again tapped; the tunica was then so thick that the needle penetrated it with difficulty; iodine was again injected. On April 2d he was tapped once more, and on April 9th he was chloroformed, and the sac excised. The sac showed marked hypertrophy consequent upon new tissue formation. Its serous surface was roughened by the injection medium. (This case is reported at length in the "Annual Report of the U. S. Marine Hospital Service for 1888.")

### EPITHELIOMA OF THE PENIS.

T. D——, aged thirty-eight, New York, admitted January 30, 1889, for ulceration of the penis and prepuce. The remains of the latter were removed under cocaine. At first it was supposed that the ulceration was phagedenic, notwithstanding the history that in January, 1888, a sore appeared on his penis, and was followed by a papular eruption on his body. Subsequently a hard growth remained at the site of the initial lesion, and in the two months previous to admission this had rapidly enlarged. The entire glans was involved, presenting a red, fungous appearance. The penis was amputated, examination having revealed the epitheliomatous character of the growth. Dr. Armstrong believed that this disease was of rare occurrence, at least it was so in the experience of the Marine Hospital Service.

### TUBERCULOSIS OF THE EPIDIDYMIS.

H. D——, aged twenty-nine, Ireland, admitted February 29, 1888. In 1886 the left testicle was injured by a blow from a truck-handle. Subsequently he was operated

on, a small portion, he said, of the testicle being removed. A deep sinus existed, at the time of admission, in the skin of the left scrotum, involving the epididymis. This was incised, but it did not heal. Its tubercular character being demonstrated by examination of the pus, the testicle was extirpated. The patient was discharged April 17th. It is of interest, in connection with the relation of local to general or pulmonary tuberculosis, that this patient was readmitted for tubercle of the lungs on November 20th, and now has large cavities.

CHRONIC ORCHITIS.

O. F. O——, aged twenty-nine, Norwegian, was admitted to the hospital January 4, 1889. In 1886 the left testicle became enlarged without cause, as far as he knows. Two years ago he was treated in New Zealand for hydrocele. An ulcer of the skin occurred at the point of tapping that never healed. When admitted there was a large ulcer of the skin on the anterior surface of the scrotum, involving the testicle. All the lymphatic glands were slightly enlarged, probably in consequence of syphilis acquired sixteen months ago. The testicle was extirpated, and on section showed almost complete fibrous degeneration, but little of the tubular structure of the gland remaining. Undoubtedly the tapping for the hydrocele was an inciting cause, and the short period occupied in the production of the degeneration (two years) is a matter of interest.

DR. F. N. OTIS said that he had been somewhat surprised to learn that epithelioma of the penis was such a rare condition in the experience of the Marine Hospital Service, for he had seen and had operated upon quite a number of cases, and was of the opinion that the disease was one of moderately frequent occurrence in private practice. The results of operation in his cases had been quite satisfactory, and in those which he had been able to follow up there had been no return of the disease.

In regard to the case of thickening of the tunica vaginalis, he asked whether, in Dr. Armstrong's opinion, the thickening was the result of the treatment—of irritation caused by the penetration of iodine. He had seen some cases of thickening of the tunica from ordinary injury. One case occurred in a boy, sixteen years of age, who was struck by a base-ball, and had a hydrocele following. This was tapped several times, and subsequently a hydrocele developed on the opposite side. Dr. Otis saw the boy some two or three years later, and then the scrotum was enormously enlarged, measuring between five and six inches in its long diameter. Several efforts were made to draw off the fluid, but without success, and at last the speaker made up his mind that no ordinary instrument could pass through the thickened tunica vaginalis, and concluded to incise it. He went down through at least half an inch of the most dense fibrous tissue before coming to the fluid. He did a Volkmann operation. No portion of the tunica was removed, yet the thickening gradually disappeared, and the boy made a perfect recovery. In other cases a similar result had been obtained, and he had found that Volkmann's operation was all that was necessary to restore the tunica to its normal proportions.

DR. ARMSTRONG did not think that the thickening of the tunica vaginalis in his case was due to the action of the iodine employed. He had at first intended to perform Volkmann's operation, but had abandoned the idea, as he feared it would not suffice to effect a cure. Since learning of Dr. Otis' experience, however, he thought that very possibly he might have been successful had he adhered to his first intention.

THE PRESIDENT remarked that the effect of the Volkmann operation upon the thickened tunica vaginalis, in the cases related by Dr. Otis, was perhaps similar to that obtained by the gynecologists in the case of subinvolution of the uterus, as a result of repairing a lacerated cervix.

DR. JOHN S. ELY presented some specimens showing

HYPERTROPHY OF THE PROSTATE, CYSTITIS, AND PYELONEPHRITIS.

"The patient, an American, sixty years of age, first came under observation toward the end of November, when he presented himself at Bellevue Hospital with retention of urine. A soft rubber catheter was passed without difficulty. Enlarged prostate and cystitis were diagnosticated, and the bladder was washed out with one per cent. boric acid solution daily till all pus disappeared. He was then taught to use a soft rubber catheter, and was discharged. He returned to the hospital on January 4th, again with retention, which was easily relieved. Toward the end of January thick pus was noticed to be flowing from the urethra, and abscess of the prostate was diagnosticated. Dr. Hall performed external urethrotomy. The man did well for about a week, then had two chills at about thirty-six hours' interval, was slightly irrational at times, and had a considerable elevation of temperature. He gradually became weaker and died on February 7th of exhaustion.

"At the autopsy the prostate was found to be very much enlarged, especially the left lobe, which measured $6 \times 3\frac{1}{2} \times 3$ ctm., the whole gland measuring $6 \times 5 \times 3$ ctm. The prostatic urethra was compressed so that its lumen was completely occluded. When cut, the prostate presented the ordinary appearance of the hypertrophied organ. There was no sign of abscess.

"The wall of the bladder was much thickened ($1\frac{1}{4}$ ctm.), and its mucous membrane was velvety, congested, and covered with pus. A small amount of thin pus was in the bladder. The ureters were much dilated, the left somewhat more than the right, which measured about $2\frac{1}{2}$ ctm. in circumference. The pelves of the kidneys were also much dilated and filled with thin pus. The mucous membrane was much congested, and velvety in appearance. The capsule of the kidneys was somewhat adherent, the cortex was thickened and cloudy, and there were occasional points of light yellow color, suggesting small collections of pus. Many of the collecting tubules were much dilated.

"Microscopical examination of the kidney showed the characteristic changes of chronic diffuse nephritis, and also many collections of small round cells, with degenerating nuclei.

"Though this is but an ordinary case, I have thought it worth while to present it to-night, because the picture is so typical and because a practical lesson seems to be pointed by it. I have repeatedly heard Dr. Sands say that the liability to suppurative nephritis after operation was greatly increased by the existence of chronic Bright's disease. He always caused the urine to be carefully examined, and often refused to operate when albumin was present. When pyelitis exists the tendency to infection of the kidney must be great. So long as the strength of the patient can be kept up this may be counteracted in many cases. But weaken the patient by the additional drain upon his resources imposed by operation, and no wonder that the equilibrium before existing should be destroyed."

Dr. Ely then presented a specimen, on behalf of Dr. Hodenpyl, showing an

ENLARGED MIDDLE LOBE OF THE PROSTATE

which had caused a moderate degree of retention, though it had not given rise to very much trouble in this respect. He could give no accurate clinical history of the case.

Dr. Ely also presented a third specimen of

SUPPURATING HYDROCELE.

There was no history of the case, and the specimen had not been obtained until it had become somewhat decomposed.

DR. ARMSTRONG asked whether any strictures of the urethra had been found in the first case reported.

DR. ELY replied that there were no strictures.

Dr. Otis said that the third specimen seemed to be one of ordinary hæmatocele.

Dr. H. P. Loomis presented a specimen of

MULTIPLE ULCERS OF THE STOMACH IN A MORPHINE HABITUÉE.

"The specimen was removed from a woman, forty-two years of age, a nurse by occupation, who was admitted to Bellevue Hospital the 29th of March. Her parents died of old age. She denied alcoholic habits and a specific history. The patient was strong and well, up to twelve years ago, when she had to have her foot amputated, and as a result of attempts to relieve a severe neuralgia in the stump, she became addicted to the use of morphine. Since this time she had never been well, and had always taken morphine to excess. For the last three months she had been troubled with incessant vomiting and a severe pain in the epigastric region, and had been growing weaker and weaker.

"On admission to the hospital the patient was vomiting almost constantly; the material consisted of partially digested food, mucus, and, once or twice, some black coffee-ground material. A microscopical examination of the urine showed it to be normal. After a few days, by keeping the patient on a peptonized milk diet, giving oxalate of cerium and morphine, the vomiting stopped, the pain over the stomach improved, and the patient seemed to be doing so well that the visiting physician, after careful examination, directed that she be transferred to Charity Hospital. While sitting in the ward, waiting to leave the hospital, the patient fell over and died almost immediately.

"*Autopsy*, eight hours after death.—Lungs: the right lung was normal, with the exception of some old adhesions at the apex. The lower lobe of the left lung was bound completely to the chest-wall by new connective tissue-bands, and was almost airless; the upper lobe was normal. The heart-walls and cavities presented a normal appearance; there was some thickening at the base of the aortic and mitral valves, and the aorta was atheromatous. The spleen was enlarged and soft. The liver was of normal size, and showed the ordinary appearances of fatty infiltration. The kidneys were intensely congested; otherwise of normal appearance. The brain showed a slight opacity along the vessels of the convexity, which were intensely congested. Stomach: The organ was of normal size and empty. On opening the stomach, the mucous membrane was seen to be intensely congested, and the surface presented the ordinary appearance of a chronic catarrhal inflammation at the pyloric extremity. On the posterior surface, and near the lesser curvature, were four ulcers, the largest a half inch in diameter, the smallest the size of a pea. They were of circular shape, with 'clean-cut' edges; their floor showed no active inflammatory changes. One of the ulcers had penetrated as far as the muscular coat, another to the peritoneum, which could be seen as a thin membrane by holding the stomach up to the light. The largest ulcer had perforated, and looked like a clean hole punched out of the wall of the stomach, the edges of which were rounded and smooth. There was no evidence of peritonitis. The intestines were very anæmic and small, but no lesion was found in them."

Dr. John C. Peters said that he had seen some cases of ulcer of the stomach in which the lesions were seated in the upper portion of the organ. The patients were perfectly comfortable as long as they ate only small quantities of bland food; but a large meal would cause pain and discomfort; and, in one instance, a perforation took place in consequence of an indiscretion in this respect.

The Society then went into executive session.

---

A New Mineral Spring.—In boring an artesian well for an Indianapolis hotel, water was reached at a depth of about a thousand feet, and was found to be strongly saline. A rough analysis has shown the presence of chloride of sodium, hyposulphite of sodium, and several sulphides.

## OUR LONDON LETTER.

(From our Special Correspondent.)

TUBERCULOSIS IN SOME OF ITS SURGICAL ASPECTS—REST VS. EXCISION IN THE TREATMENT OF TUBERCULAR JOINT DISEASE—COLOR-BLINDNESS IN THE MERCANTILE MARINE—THE PROPOSED HOSPITAL INQUIRY—SPECIAL HOSPITALS AND THE METROPOLITAN HOSPITAL SUNDAY FUND—THE BRITISH MEDICAL ASSOCIATION.

London, August 5, 1889.

In Mr. Howard Marsh's concluding lecture on "Tuberculosis in Some of its Surgical Aspects," delivered at the College of Surgeons, the lecturer remarked that, speaking of the general group of tubercular diseases met with in surgery, he believed that, when they were detected early and were adequately treated by prolonged rest, in not more than at the most ten per cent. did they develop to any formidable degree. It was a rule to which he had seen but few exceptions, that when, for example, a knee or an elbow, which was the seat of tubercular disease of less than three months' duration, was enclosed in well-fitted splints and kept at rest, the case gave no further real trouble. The symptoms began at once to subside, and the improvement, though slow, went on without material check until the joint was apparently free from disease; while, after a longer period of rest, complete recovery was secured. In early cases the period required for treatment did not, as a rule, exceed twelve or eighteen months, and he had met with many cases in which, after this time, no trace of disease beyond slight muscular wasting remained. In more advanced cases, though the period occupied was longer, the same treatment would lead to good repair. His experience as to caries of the spine accorded with what he had seen in the joints. When prolonged rest was secured, though these cases were tedious—for tubercle, once deposited, could not be got rid of quickly—there was nothing inveterate about them. Tney responded at once to treatment, and steadily improved; in the great majority complete recovery, though often with some degree of deformity, took place. They became unmanageable only when they had been allowed to advance for a twelvemonth and upward before treatment was commenced. In fact, it was with caries of the spine as it was with diseases of the joints. Early diagnosis and adequate treatment would lead to recovery, but if the process were allowed to advance month after month, or year after year, neither present nor future surgery could bring about satisfactory results. General tuberculosis occurred in some instances as the result of infection, either from any of the joints or from the spine. He had occasionally seen such cases, but he felt convinced that the percentage here was much the same as in the case of the hip-joint (in the preceding lecture Mr. Marsh estimated this as five per cent.).

After discussing at length some statistics relating to the subject, the lecturer observed that if we placed the results of excision, so far as recorded, side by side with the results of continued rest, there could be no doubt as to the conclusions at which we must arrive. Referring to various published series of cases in which the mortality varied from sixteen to thirty-six per cent., Mr. Marsh said he was confident that in cases of suppuration treated without operation the mortality was not more than ten per cent., and his strong impression was that it was materially less than this. As to the ultimate condition of the limb, our information as to the results of excision was limited. Some of these results were quoted, but the lecturer said he did not doubt that, as operative surgery improved, the immediate results of excision would be greatly superior to those referred to. They would be so good, especially when the operation was performed early, that, unless the results to be obtained without operation were kept well in

view, excisions would, he ventured to think, be performed much too commonly. It must be remembered that the mere healing of a wound did not show that an operation was the best thing for the patient, or afford any proof that it ought ever to have been undertaken. The main defect of excision was in the ultimate result as regarded the usefulness of the limb, when this was compared with a limb in which no operation had been performed, and in which the joint, instead of having been removed, had been restored to that considerable degree of usefulness which could generally be secured by rest. He believed it was now generally recognized by most surgeons that, although the immediate result of excision of the knee, in children, might be all that could be desired, yet the ultimate result was unsatisfactory. The union between the bones gradually yielded in many cases, the bones grew imperfectly, deformity ensued, and the functions of the limb were materially interfered with. He thought it would be much the same in the case of the hip. In both cases alike—in the knee and in the hip—when one of the principal joints of the lower extremity had been removed during childhood the patient had been seriously crippled.

A good deal of attention has of late years been given to the subject of color-blindness, not only in professional but in lay circles. The danger of allowing color-blind persons to engage in certain occupations, such as those of seamen and railway men, has been repeatedly pointed out by ophthalmic authorities. It is therefore satisfactory to find that the Government has appointed a departmental committee to investigate the subject of color-blindness among the seamen of the mercantile marine. The report of the committee, however, will not be laid before the House of Commons till next session.

On Monday last, in the House of Lords, the long-talked of petition (promoted by the Charity Organization Society) in favor of an inquiry into the working of voluntary and other medical institutions in the metropolis was presented by Lord Sandhurst. In doing so he referred to the various branches of the subject, pointing out some of the abuses known to exist. The President of the Privy Council, while mentioning some of the difficulties which beset the subject, said that the Government would consider the case for inquiry, and next session he might be able to announce what course they proposed to take. I am not very sanguine that the proposed inquiry, if held, will lead to much. Apart from the difficulty of interfering with institutions supported by voluntary contributions, there is the still more serious one of rival and conflicting interests to be dealt with. The most that can be hoped from a public inquiry is that it will bring the force of public opinion to bear upon institutions in which wasteful methods of management are in force, and thus lead to wise economies being enforced. A good deal has been recently said against special hospitals. There is no doubt that these are too numerous, and yet during the last few years new ones have been springing up like mushrooms—soon, in most cases, to get deeply involved in debt. It is significant that the Hospital Sunday Fund have this year refused the usual grant to two special hospitals, viz., St. John's Hospital for Skin Diseases and the West End Hospital for Diseases of the Nervous System.

It was lately announced that the annual meeting of the British Medical Association would be held in London next year. It was supposed of course that the matter was settled, and that the acceptance (in the general meeting at Leeds) of the invitation of the Metropolitan Counties Branch was merely a formality remaining to be done to clinch the matter. It appears we were mistaken. Some of the wire-pullers connected with the Branch want to undo this, and have accordingly summoned a meeting for to-morrow at which they hope, by a snatch vote, to rescind the vote given at the annual meeting of the Branch a month ago. No doubt the plan may succeed, especially considering that many members of the Branch have now left town. If so, offence will doubtless be given to many, but the executive of the Association will care little for that. They are indeed past masters in the art of giving unnecessary offence. If any illustration of this were needed, it would suffice to refer to the manner in which a letter to the *Journal* from a well-known hospital surgeon was recently suppressed, while at the same time an insulting paragraph animadverting on the writer was inserted,—to which, however, he was not allowed to reply.

## OUR PARIS LETTER.

TREATMENT OF INTESTINAL OBSTRUCTIONS BY ELECTRICITY—HEREDITARY MYOPIA — A NEW FORM OF TUBERCULOUS DISEASE—THE SECOND CONGRESS FOR THE STUDY OF TUBERCULOSIS—HONORS TO DR. NACHTEL.

PARIS, August 2, 1889.

ABOUT twelve months ago Dr. Larat read a note at the Academy of Medicine on the treatment of intestinal obstructions by electricity. At the meeting of the Academy of last week Dr. Hérard read his report on the merits of the work. After having analyzed some of the observations related by Dr. Larat, Dr. Hérard considers that in presence of an intestinal occlusion, before having recourse to laparotomy or the formation of an artificial anus, one must first employ purgatives; if these do not succeed, belladonna, full doses of opium in subcutaneous injections, enemata of siphons of seltzer water, and finally, electricity should be employed. The mode of electrization which appeared to give the best results in acute strangulation is faradization. On the contrary, in the forms of intestinal occlusion which are slow in their course, accompanied with intestinal paresis, galvanization succeeds the best. In order to insure a proper action one must employ, simultaneously, inducted and continued currents. M. Boudet, of Paris, a well-known electrician, in the first instance, then Dr. Larat, had the happy idea of disseminating the galvanic electricity over a larger surface of the intestinal mucous membrane by means of an enema of salt water. This method appears to be the most efficacious. Dr. Le Fort thinks that it is necessary to make some reserve on this method of treatment, as, after all, Dr. Larat counts only ten cures out of twenty-four cases, and of these cures it is probable that some of them were cases not of true intestinal obstruction, but of obstinate constipation. He thought that it was well to employ electricity when one was in the presence of a patient presenting the symptoms of an intestinal occlusion; but, if this should not succeed in the twenty-four hours, one must without hesitation intervene surgically. It will be remembered that Dr. Duchenne de Boulogne was the first to try to overcome intestinal obstructions by the action of faradic electricity. Since then it has been remarked that smooth muscular fibres, like those of the intestines, were more sensible to the galvanic current; but the formation of eschars was feared, and the employment therefore of the continued current is exceptional. By an ingenious arrangement, however, adopted by M. Boudet, all danger is averted. One of the poles is formed by a large plate placed in contact with the abdomen, the other by a metallic stem enclosed in a sound of India-rubber, which is introduced into the rectum. The sound has an isolating property, so that, to pass the current, one introduces into the rectum one litre of salt water, which establishes the contact between the metallic stem and the intestinal parietes. Dr. Constantin Paul remarked that it was better to place in the intestine the negative, and not the positive pole, as recommended by Dr. Hérard; by this means one obtains more energetic intestinal contractions.

Dr. Duclaux communicated to the Academy of Sciences, in the name of Dr. Boucheron, a note relative to hereditary myopia and its treatment in adolescence. The children of myopes are not born myopes, they become so, but at an age more and more young, according as generations succeed. Thus, a grandfather who became myopic at twenty years, having a son myopic at fifteen years, they

would both have a slight myopia, and would be able to read without spectacles in their old age; but their grandchildren will become myopic at twelve years, and will already have been so to a great degree. The great-grandson will be a myope at eight years, will arrive at six dioptrics of myopia at fifteen years, at eight dioptrics at thirty years, will lose an eye at thirty-five years, and will have great difficulty in preserving his second eye to the end of his days. It is therefore necessary that this state of things should be more rigorously attended to. Dr. Boucheron remarked that in children somewhat the same thing happens with the muscles of the eye as what occurs in writer's cramp. The child strains in writing, contracts himself and there is produced cramp of the accommodation of the eye, and this abnormal accommodation tends to become permanent in myopic pupils. Dr. Boucheron examined 100 lycéens, and took the measure of their myopia. He instilled atropine into their eyes, and their myopia was modified. Hence, beyond the principles of hygiene, so easy to institute, he recommends the employment, in feeble doses, of atropine, duboisine, or simply cocaine.

M. Chauveau presented a note at the Academy of Sciences, for Dr. Curmont, Preparator at the School of Medicine of Lyons, on a new bacillary tuberculosis of bovine origin. The bacillus of Koch commits in the bovine species the same ravages as in the human species. But there exist other bacilli which also engender tuberculosis in oxen. Dr. Curmont has just discovered one, which is very singular by its morphological and physiological characters. This bacillus inoculated into the rabbit also determines tuberculosis, it invades not only the principal organs but also the blood. Inoculated into the guinea-pig it does not communicate tuberculosis to it, but it produces a general infection which is fatal. If, with the residues of its culture, one tries to determine, as is done habitually, immunity by inoculations, not only this immunity is not obtained, but, on the contrary, the animal is rendered more apt to contract infection. The guinea-pig dies in twenty-four or twenty-five days after the simple injection. After the inoculation and the new injection it dies much more rapidly in a few days. These facts are very singular, and in contradiction with what we have known till now.

The Second Congress for the Study of Tuberculosis will take place at the end of July, 1890, under the Presidency of Professor Villemin. The following questions are proposed for discussion: 1. The identity of tuberculosis in man and of that in cattle, fowls, and other animals. 2. The bacterian and morbid associations of tuberculosis. 3. The hospitalization of tuberculous subjects. 4. On the agents capable of destroying the bacillus of Koch, non-injurious for the organism, in regard to the prophylaxis and to the therapeutics of human and animal tuberculosis. Adhesions and subscriptions (twenty francs) are to be forwarded to M. G. Masson, Treasurer, 120 Boulevard Saint Germain, and all which concerns communications for the Congress should be addressed to M. le docteur L. H. Petit, General Secretary, 11 Rue Monge, Paris.

Dr. Nachtel, on the recommendation of the Minister of Public Instruction, has been nominated an officer of the Academy of France, in recognition of his great services in connection with the city ambulances.

## ELECTROTHANASIA.

To the Editor of The Medical Record.

Sir: Ever since the passage of the law in this State requiring the use of electricity as a means of capital execution, there has been much discussion as to the method of employing it, the apparatus, human resistance, the possibility of killing at all, etc. I say *since* the passage of the law, for, singularly enough, the method was legally adopted before any practical point had been settled with regard to electrothanasia (the writer would suggest the use of this word in the place of such a barbarous term as "electrocution," which appears in some of the daily papers). The commission that drafted the law had a few dogs killed at Buffalo in the following manner: They were partly immersed in a zinc-lined box containing water, which served as one pole; the wire of the other pole was inserted into the mouth or wound around the nose. The current was furnished from an electric light wire. It was upon such experiments as these that the new law was based! As to the electromotive force, the resistance, the current strength, the kind of current used, not one of these facts seems to have been known or noted.

In the summer of 1888, Mr. H. P. Brown, a practical electrician of this city; Mr. A. E. Kennelly, chief electrician of the Edison Laboratory, and the writer, made a large number of careful experiments upon lower animals, but not for the purpose of determining any facts concerning the employment of lethal currents in execution.

One object was to study the well-known differences between high-tension continuous and alternating currents, both of which have been fatal to many human beings in this country, and whose dangerously high voltage has been limited by law in England and France; and another object was to observe the physiological and pathological effects of death-currents (*Electrical World*, August 11, 1888). In all, some twenty-four dogs were killed. Subsequently the writer was made chairman of a committee of the New York Medico-Legal Society, to report upon the best method of execution by electricity, and the experiments already undertaken were found to have valuable application in a study of this subject. Additional experiments were conducted before this committee and a number of State prison officials, several calves and horses being killed. The committee then recommended, in legal procedures, the application of good-sized, metallic, sponge-covered electrodes to the head and spine, after careful saturation of the skin and sponges with a warm saline solution; the use of a 3,000 volt dynamo, and a current potential of 1,000 to 1,500 volts, alternating 300 times per second, for a period of time, from fifteen to thirty seconds.

There is no doubt that the current thus applied will kill in every instance without regard to human resistance, and that unconsciousness, and cessation of pulmonary and ventricular movements will be instantaneous.

The objections, upon the ground of enormous human resistances, so ably set forth by Dr. Sachs, in his letters to The Medical Record of July 27th and August 17th, can be met by accurate statements of facts already known.

In the first place, the writer does not dispute the correctness of Jolly and Gärtner in their determination of resistances in the human body amounting to as much occasionally as one-half of a megohm; but it must be borne in mind that this resistance is the initial resistance to exceedingly small electromotive forces, even as low as one volt, to which even less than 500,000 ohms would seem to be almost complete insulation. The strong current referred to by Dr. Sachs as reducing the resistance of the feet from 22,000 S units to 20,000 in a minute, had certainly not over forty volts as its electromotive force.

Now it is a fact that the greater the electromotive force the more rapidly is resistance reduced, and this is especially true of interrupted and alternating currents. For instance, the primary current of a faradic battery, which is an interrupted, and the secondary, which is an alternating current—neither one of these appears to meet with much resistance in the human body, for after the skin and electrodes are moistened the effect upon the sensory-motor apparatus of closing the circuit is so instantaneous that one almost questions whether there is any resistance at all. To be sure the electromotive force is quite high in a faradic battery, as it is multiplied by every turn of the coils, and this may explain the sudden overcoming of resistance. The writer is not aware of any special study having been made of resistance in connection with faradic

currents, with interrupted galvanic currents, or with "voltaic alternatives," which, if made to occur two to three hundred times per second would be our industrial alternating current. But the animals sacrificed last summer were carefully measured as to their resistances, and some of the facts then obtained have value as an argument here:

A dog with 7,500 ohms resistance took 800 volts of a continuous current for two seconds. During the two seconds the index of the ammeter rose rapidly to 1 ampère, which was as high as the instrument was made to register. Hence the resistance dropped from 7,500 to 800 ohms, or less, in two seconds. Another dog, with 6,000 ohms resistance, received one instantaneous shock of a 1,000 volt continuous current. The ammeter gave its full register of 1 ampère. Hence here was an instantaneous fall from 6,000 to 1,000 ohms, or less. A third animal, with 27,500 ohms resistance, received 160 volts of an alternating current for five seconds, causing immediate death. As the ammeter could not be used with this form of current, we were unable to determine the current strength. But surely the resistance must have been enormously reduced in five seconds, $\frac{160}{27500} = \frac{16}{2750} = \frac{1}{171.8}$, or nearly 6 milliampères, which of course did not kill the animal. Supposing even that as little current as one-tenth of an ampère killed the dog, we have a fall in five seconds from 27,500 to 1,600 ohms!

Further instances need not be cited, but attention should be called to the fact that the resistances of these dogs, as given, must be considered as minimal rather than maximal, and do not therefore represent the much larger initial resistances that these strong currents overcame at the first instant of closing the circuit.

As regards differences in resistance between man and the lower animals, they cannot be great, and must be due to analogous causes. In dogs, calves, and horses, the resistance was found to vary between 1,300 and 200,000 ohms, while in man it has been shown to vary from some 600 to some 500,000 ohms. Bones, muscles, saline fluids, viscera, do not differ so much in the human and lower species that these resistances can be said to be due to variation in their composition; but the skins containing these tissues do vary widely in thickness, blood and sweat supply, and hairy and epidermal coverings, not only in various species of animals, but in different parts of any individual of any species. At the same time, minimal resistances do not differ greatly between men, provided similar parts be subjected to the same treatment for the purpose of measurement.

The experiments made by Mr. Kennelly recently for Mr. Edison were conducted upon three hundred persons. The hands were immersed in very dilute KHO as far as the wrist, and every measurement was taken as nearly as possible thirty seconds after the beginning of the passage of the current. No resistance exceeded 2,000 ohms, the average being 1,000. Doubtless the initial resistances, say in the first two or three seconds, would have been vastly higher with the small voltage employed; yet could anyone say that a 1,500 volt continuous current would not have been dangerous to life under these same conditions to every one of these three hundred persons during the first five seconds of contact? And if, instead of a continuous current, a 1,500 volt interrupted current, or 300 "voltaic alternatives" per second from a 1,500 volt dynamo had been used, could anybody bring forward one single fact to prove that death would not have taken place in every instance within ten or fifteen seconds?

These facts have been adduced by the writer from an impartial stand-point, for he would disclaim looking with any favor upon electrothanasia as an ideal method of legal execution; and, indeed, is opposed to it, but upon other grounds than its uncertainty.

It is absolutely certain, if the apparatus and circuit are in perfect order. But the tetanic rigidity into which the victim is always thrown, the relaxation of the sphincters of the bladder and rectum generally occurring during the contact, and the necessity of extraordinary care in the arrangement of the apparatus by an expert electrician, render it far from a desirable means for the legal extinction of human life.

FREDERICK PETERSON, M.D.
201 WEST FIFTY-FOURTH STREET.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 11, to August 17, 1889.*

By direction of the Secretary of War a board of medical officers, to consist of Lieutenant-Colonel ANTHONY HEGER, Surgeon; Captain JOHN O'SKINNER and Captain JAMES C. MORRILL, Assistant Surgeons, will assemble at the U. S. Military Academy, West Point, N. Y., on August 25, 1889, or as soon thereafter as practicable, to examine into the physical qualifications of the candidates for admission to the Academy. Par. 9, S. O. 185, A. G. O., August 12, 1889.

GARDNER, WILLIAM H., Major and Surgeon, Washington Barracks, is hereby granted leave of absence for one month. Par. 1, S. O. 183, Headquarters Division of the Atlantic, Governor's Island, New York City, August 13, 1889.

MATTHEWS, WASHINGTON, Major and Surgeon. Promoted to Surgeon, with rank of Major, to take effect from the 10th day of July, 1889, vice Town, promoted. War Department, Washington, D. C., August 14, 1889.

HAVARD, VALERY, Captain and Assistant Surgeon, is granted leave of absence for one month, to take effect about October 1, 1889, with permission to apply to Division Headquarters for an extension of one month. Par. 3, S. O. 86, Department of Dakota, St. Paul, August 10, 1889.

PORTER, JOSEPH Y., Captain and Assistant Surgeon, now at Jacksonville, Fla., by direction of the Secretary of War will, if the state of his health permit, proceed to Jackson Barracks, La., and report to the commanding officer of that post for temporary duty, and by letter to the commanding general, Division of the Atlantic. Par. 16, S. O. 186, A. G. O., August 13, 1889.

FRENCH MODESTY.—A Parisian medical society recently appointed a committee to consider the question of a universal language of science. The report of the committee was presented in the form of three questions, upon which the society voted as follows: "Shall a universal language be adopted?" "Yes." "Ought this to be one of the dead languages?" "No." "Shall it be the French language?" "Yes."

### ON THE COMPARATIVE STUDY OF DISEASES OF THE NERVOUS SYSTEM.

BEING THE ADDRESS IN MEDICINE DELIVERED BEFORE THE BRITISH MEDICAL ASSOCIATION.

BY J. HUGHLINGS JACKSON, M.D., F.R.C.P., LL.D., F.R.S.

PHYSICIAN TO THE LONDON HOSPITAL, AND TO THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC.

FIRST of all, I beg the President and Council of this great Medical Association to accept my heartiest thanks for the very high honor they have conferred on me in asking me to give this address. I have had much difficulty in choosing a subject, the difficulty being mainly in finding one on which I thought I had something to say, and on which I had not already said the little I was capable of. Finally, I concluded to consider once more, with all the care I could and with as little recapitulation as possible, the most important of general doctrines bearing on the science of medicine.

We have multitudes of facts, but we require, as they accumulate, organizations of them into higher knowledge; we require generalizations and working hypotheses. We have, so to speak, ready made for us, the hypothesis of evolution, one verified in numerous different cases. Huxley[1] writes: "The peculiar merit of our epoch is that it has shown how these hypotheses [one of which is the doctrine of evolution] connect a vast number of seemingly independent partial generalizations; that it has given them that precision of expression which is necessary for their exact verification; and that it has practically proved their value as guides to the discovery of new truth." I do not advocate the application of the doctrine of evolution to the classification of diseases for practical purposes, but believe, nevertheless, that its indirect value to clinical medicine is very great indeed, and that before long it will be directly helpful. Thinking that for clinical purposes we must continue to have arrangements of cases "by type."[2] I once more urge that we should also attempt a parallel study of diseases as they are dissolutions—that is, reversals of evolution. By the latter means I hope that we shall be able to make broad and yet precise generalizations of great value. The man who puts two old facts in new and more realistic order deserves praise as certainly as does the man who discovers a new one. There is an originality of method. Gaskell has found out much that is new in his recent well-known researches on the nervous system; but I imagine that the greatest merit of his work is that he has made fruitful generalizations, and has set many things long ill assorted in realistic order. By doing this he will have put a stop to certain loose explanations in which the sympathetic figures. I do not pretend to be able to define generalization as that term is used in science. May I say that it is the classification of things which are for the most part very different by some fundamental peculiarity each of them has? It is easy to see how one may be misunderstood when making generalizations after this fashion; one may be supposed to overlook important differences—not to be putting things in order but to be trying to organize confusion. I will give a series of illustrations of the method spoken of, because it is one I follow largely in this address.

1.[1] A patient of mine had lost one hand, but, as is most often the case, he had, representing it, a phantom hand; this was always in a position as if encircling a vessel; the member had been blown off when he was holding a cylinder to be charged with an explosive. 2. An aphasic patient of mine frequently uttered, on being questioned, but with no relevance to anything going on, "Come on," or "Come on to me;" he was a signalman, and had been taken aphasic and hemiplegic on the railway in front of his box; the presumption is that he was saying, or was about to say, those words when taken ill. 3. An epileptic patient told me that his first fit occurred when he was a soldier, and at the very time he was "numbering off;" after every subsequent fit, and before regaining consciousness, he used to count; this we observed when he was in hospital. 4. A woman I was asked to see in a surgical ward in the London Hospital, who had fractured her skull by a fall when laying down oil-cloth on a staircase, kept, during partial unconsciousness a few hours before death, manipulating the counterpane of her bed. We supposed this to be a sort of continuance of the action of laying down the oil-cloth; the patient desisted, for a time at least, when the nurse assured her that "it was properly laid."

These illustrations will appear incoherently grouped to those who do not happen to see that the intention in stating them is not to deal with stumps, aphasia, epilepsy, and injury to the head, but to make a basis for the discovery of the reason why there is a fixation of states, which are normally temporary, upon the sudden occurrence of lesions of the nervous system;[2] very different cases are chosen in order to make the basis a broad one. This is by way of illustration, but I hope that such facts are of some value toward the methodical study of persisting delusions. I suggest, quite hypothetically, that some very grotesque delusions may be a fixation of absurd beliefs in dreams in cases where a sudden morbid change, or sudden increase of it, has occurred in the brain during sleep—such delusions as one mentioned to me by Dr. Savage; a patient of his believed himself to be a jar of Indian pickles.

Before going further, I must mention that most valuable work has been done by Anstie, Ross, Ribot, Mortimer, Granville, Mercier, and Bland Sutton in the application of the principles of evolution to normal and abnormal conditions of man's body. We ought not to forget that nearly half a century ago Laycock extended the doctrine of reflex action to the brain, and that so long ago as 1829 Von Baer announced "his great discovery, that the progressive change from homogeneity to heterogeneity is the change in which organic evolution essentially con-

[1] Reign of Queen Victoria, vol. ii., p. 340.
[2] British Medical Journal, July 14, 1888.

[1] In his magnificent work, Diseases and Injuries of Nerves, 1872, p. 355, Weir Mitchell writes as follows: "E. C——, aged thirty-two, lost his left arm, five inches below the shoulder, nine years ago. When shot, the thumb turned into the palm, and continued in this state of spasm, so that when, six hours later, the limb was removed, the nail of the thumb had cut into the palm. He several times lifted the thumb, but it always returned to the same spot. For nine years the absent thumb still remains cutting into the palm." After speaking of various positions of phantom parts of limbs, Weir Mitchell writes (*op. cit.*, p. 354): "Another class has the hand constantly in some painful position which it occupied before the operation, so that the last real sensation is so stamped upon the sensorium as to forbid its erasure by any future impression."

[2] In the case of No. 1 the hand was blown off at a time when particular nervous arrangements of the nervous centres, from highest to lowest, were being discharged. The persisting memory, so to call it, of the last position of the lost hand implies a persisting state in the highest centres. Why that state remained permanently it is for me impossible to say.

sists."[1] I need scarcely mention the name of Herbert Spencer, except to express my vast indebtedness to him; the first edition of his "Principles of Psychology" appeared so long ago as 1855, five years before the publication of the "Origin of Species."

In the doctrine of evolution we have principles which no doubt apply to the whole organism and to every one of its diseases; it is at once a means of scientific classification and a guide to the discovery of new facts. Limiting myself in this address to the nervous system, I submit that ultimately those principles will help us to a more realistic explanation of symptomatologies so different as those in a case of paralysis of an external rectus and those in cases of insanity. The comparative study of nervous diseases—the study of them as dissolutions—is a process of generalization. To attempt this generalization without prior careful analysis of the things concerned, needing minute clinical study of individual cases, is not likely to lead to anything of permanent value. To compare and contrast the mere local lesions and the symptoms directly dependent on them only in the two cases instanced is not good method. The symptomatology of each must be regarded as the result of a flaw in an evolutionary whole. It is one merit of the method I am urging that it deals not only with the local lesion—with that, I mean, which disease (in the strict sense of pathological change) causes—which alone is dissolution, but also with the healthy rest; that is, it takes into account the evolution going on in the undamaged remainder of the nervous system. The full symptomatology of a case of ocular paralysis is not to be intelligently stated even unless activities of healthy centres, including the highest (all centres above the peripheral lesion) are considered; and a case of insanity is not properly analyzed unless undiseased parts of the highest centres and all lower centres are considered (*vide infra*). In the two cases a great part of the symptomatology is owing to over-activity of perfectly healthy nervous arrangements; the erroneous projection and diplopia in the first, and the illusions, delusions, and all other positive mental symptoms in the second. To insist on the principle implied, I say in recapitulation that every case of nervous disease is a problem, not only in dissolution but in evolution: in example, he who is studying the physical process during an illusion in an insane patient, is as certainly dealing with evolution as he is who is studying that process during the perception of a healthy person.

Before I give particular illustrations of dissolution, I will make brief statements concerning some different aspects of the one process evolution, of which dissolution is the reversal: (1) evolution is a passage from the most to the least organized. I must stay to remark on the term organized. "Highly organized," is frequently used synonymously with "very complex;" but by degrees of organization I mean degrees of perfection of union and certainty of action of nervous elements with one another. Using the term organized in this sense, I say that the highest cerebral centres are the least organized (the "most helpless centres"), although they are the most complex, whereas the lowest centres are the most organized, although the least complex. In other words, we may say (2) that the evolutionary ascent is from the least to the most modifiable. If the highest centres were not modifiable, we should be very simple machines; we should make no acquirements. If the lowest ("vital") centres were to become as modifiable as the highest are, life would cease. It is only another aspect of this statement—that the progress in evolution is from the most to the least organized—to say (3) that the passage is from the most automatic to the most voluntary (properly, "to the least automatic"); equivalently, it is (4) from structures inherited most nearly perfected (acquirements of the race and of prehuman beings), such as the cardiac centres in the medulla oblongata (some centres of the lowest level of evolution)—from those comparatively perfectly evolved at birth—to those of the highest nervous arrangements of the highest centres, which are only incipient nervous structures, and which are evolving during the latest new mental states; (5) the process of evolution is from the simple to the complex; (6) from the general to the special. Reversals of evolution are effected by pathological processes, and are called dissolutions; they are reductions from the least organized, etc., toward the most organized, etc.

I can give no good illustrations of dissolution from lesions at the periphery. Nor can much that is definite be said in this regard of lesions of the spinal system (lowest level of evolution of the central nervous system). Yet we may say that in most cases of the ordinary form of progressive muscular atrophy the muscles first morbidly affected are the small muscles of the hand, and that in most cases of Duchenne's bulbar paralysis the tongue is first invaded. In these two cases the most special parts, in manipulation and in articulation respectively, fail first. Going higher up in the nervous system we find definite and certain illustrations. It is plain that hemiplegia from disease in the mid-cerebral region is a failure in the order from "most voluntary" toward most automatic; whether chorea and paralysis agitans are due to morbid changes in the region mentioned or not they certainly illustrate dissolution in the very same way as hemiplegia does. The numerous different phenomena of cases of aphasia are the best illustrations of the process of dissolution, but I have stated them several times.[1]

Dr. Donald MacAlister has pointed out, in his admirable Croonian Lectures,[2] that the febrile process exemplifies dissolution. "The thermal nervous system," to use his words, "has three parts; let us call them briefly the thermotaxic or adjusting, the thermogenic or producing, and the thermolytic or discharging mechanism. . . . In the ascending scale of evolution," he continues, "we seem to rise from the thermolytic to the thermogenic, and thence to the thermotaxic nervous system." He considers fever as a process of dissolution, and, next, recovery from fever as a process of re-evolution. Some, presumably all, cases of insanity illustrate dissolution. I will content myself with quoting very briefly from that part of Dr. Savage's important work, "Insanity," where he deals with general paralysis. In these cases, he writes, that the disease "affects first the highest intellectual and motor acquirements is undoubted." He says, too, "Both Dr. Maudsley and I have independently taught that in this progressive degeneration the last and highest acquirements fail first." . . . We have very good illustrations of dissolution in the symptomatology of drunkenness. Long ago Charles Bell wrote:[3] "It is a fact familiar to pathologists that where debility arises from affection of the brain, the influence is greatest on those muscles which are, in their natural condition, most under the command of the will. We may perceive this in the progressive stages of debility of the drunkard, when successively the muscles of the tongue, the eyes, the face, the limbs, become unmanageable; and under the same circumstances, the muscles which have a double office, as those of the chest, lose their voluntary motions and retain their involuntary motions; the force of the arms is gone long before the action of breathing is affected."[4] Lauder Brunton, in his "Pharmacology," third edition, p. 146, writes: "In the action of such poisons as alcohol, the nervous system appears to be paralyzed in inverse order of its development; the highest centres going first, next the middle, and then the lowest. After this comes paralysis of the motor nerves, and, lastly, of the muscles themselves."

I now give a curious illustration. We see, not dissolution, but, this time, evolution illustrated by certain surgical cases—by the order of persistence of spectral repre-

[1] Fiske: Cosmic Philosophy, vol. i., p. 342.

[3] Nervous System, 3d ed., p. 165.
[4] My friend and colleague, Dr. Gowers, drew my attention to this passage: I gave the quotation, Lancet, February 15, 1873 (On the Anatomical and Physiological Localization of Movements in the Brain).

sentatives of parts of limbs lost by amputation. Weir Mitchell writes:[1] "The limb is rarely felt as a whole; nearly always the foot or the hand is the part more distinctly recognized, and, on careful questioning, we learn that the fingers and toes are readily perceived; next to these the thumb; then more rarely the ankle or wrist; and, still less frequently, the elbow and knee. Very often some fingers are best felt, especially the forefinger." This, the order in which the lost parts remain most vividly represented in consciousness, is almost exactly the order in which the parts physical do fail in dissolution of the nervous system.

Speaking most generally, and ignoring some very obvious qualifications, we may say that the hemiplegic man is reduced to a more automatic condition of movement, the aphasic to a more automatic condition of language, and the insane man to a more automatic condition of mind. There is a reduction to a lower level of evolution in each series.[2] Dissolution is exemplified in each of the following exceedingly different symptoms: 1. Most epileptiform seizures begin in the thumb or index finger, or in both; these digits are the most special parts of the body. 2. The words most often left to an aphasic who is, for the rest, entirely speechless, are "yes," or "no," or both; these "words," as I called them, are the most general of all propositions. 3. The aphasic may be unable to put out his tongue when told, although he moves it well in other ways; loss of the "most voluntary" movement, with persistence of the more automatic movements of that organ. 4. In what is called word-blindness there is inability to recognize the latest learned, and very arbitrary, "objects," letters, and words, while the recognition of objects, properly so-called, is unimpaired, or comparatively so. 5. In early stages of atrophy of the brain, say, in that occurring so often after hemiplegia in men past middle age, there is defect of memory for recent events with seemingly good remembrance for long past circumstances, and there is at the same time loss or defect of the "finest," latest acquired emotions, with obtrusion of the coarser and earlier acquired. Different as these five examples are, they are alike in that dissolution is definitely illustrated by each of them.

I here stay to remark on what I think is the evolutionist's measure of mind. Opinions will differ vastly as to who are the men of greatest mental elevation. Some would put Napoleons highest, others Shakespeares and Goethes. But evolution, I think, supplies us with a scientific measure, which ignores superior and inferior, as these terms are ordinarily used with regard to men's minds. This measure is according to the intellectual and emotional differences between lower and higher races of mankind, and to those between children and adults. Higher races of men and adults have the latest acquired faculties, and these, according to Spencer, are, intellectually, the power of abstract reasoning, and, emotionally, the sentiment of justice. So that, instead of saying that a person is superior or inferior to most other men, we may say that he has more or less of the latest faculties of the race that most other men have. I by no means think that to have the latest intellectual faculties most highly developed is the same thing as being most endowed intellectually. I submit that the poet inherits in some ways more of the earlier acquired faculties of the race, and has less of the latest than the scientific man has; yet no one would say that poets are mentally inferior to scientific men. In the cases of atrophy of the brain recently instanced, there first occurs defect of the two "latest" faculties I mentioned; the patient easily becomes confused by consideration of things of a little complexity, and of which the elements are not before him, and is often peevish and selfish.

[1] Op. cit., p. 350.

[2] Dr. Mortimer Granville, who has for some years applied the doctrine of dissolution, uses the term "denudation," and takes note of the "exposure" of the lower layers, which I call the lower levels of evolution, remaining.

I admit that I have selected cases which will suit my purpose best. Some cases seemingly exceptional are not so. It is not meant that in every case of nervous disease the most voluntary of all parts of the body suffer first and most. Were that so all nervous diseases would affect first and most the thumb and index-finger. The word voluntary, a psychological term, is not the right word to use when speaking of physical processes. The progress of dissolution, properly stated on this aspect, is from the least automatic toward the most automatic. And in disease of any centre it is only supposed that the "most voluntary" (least automatic) parts represented by that centre suffer first and most. In an epileptiform seizure, beginning in the leg, the great toe is nearly always the part first in spasm; the "most voluntary" part of the leg suffers first and most from the cortical discharge.

To take a more extreme illustration. It may be said that the symptoms from morbid changes in the cerebellum do not accord with statements made as to the process of dissolution. I believe that all the skeletal muscles are represented in the cerebrum in one set of movements, and that all of them are represented in the cerebellum in another set of movements. In rough and only partial statement the order of representation in the cerebrum is of movements of the arm, leg, and spine. This agrees with a popular doctrine, for the order is that of the degree in which the three parts of the body are "under command of the will." The order of representation in the cerebellum is of movements of the spine, leg, and arm. This accords with the current doctrine that the cerebellum co-ordinates (*vide infra*) movements of locomotion. (I presume that a man's spine must be braced up before his legs can come into play in walking.) So that, ignoring the term voluntary on account of its psychological implications, and using the term special, we say that the arm is the most special part in the cerebral series, and fails first in disease of the brain proper; and that the back is the most special part in the cerebellar series, and fails first in disease of the cerebellum.

I now try to consider evolution and dissolution more methodically. I submit the following statements: By aid of the doctrine of evolution we shall discover a harmony or rational parallelism between (1) psychology, (2) the anatomy and physiology of the nervous system, and (3) that important part of clinical medicine which deals with diseases of this system. It will help us toward a comparative study of all diseases of the nervous system, and in particular to the realistic comparison and contrast of cases of insanity—diseases of the highest cerebral centres—with diseases of lower centres.

The doctrine of evolution implies that the whole nervous system has a sensori-motor constitution. It has long seemed to me that only on this basis can we show how it is that such very different sets of symptoms as convulsion and insanity (and, as I think, paralysis) are owing to disease of the cerebrum proper. The assignment of such a constitution to the whole of the nervous system shows that, when I speak of diseases of that system, reference, explicit or implicit, is always to parts of the body. (By "parts of the body," I mean non-nervous parts.) It is a merit of the method that parts of the body are necessarily taken into account in all nervous lesions. The nervous system by itself is a functional nothing; it is only something as representing parts of the body.

I carry the doctrine of sensori-motor constitution of the nervous system further than anyone else, so far as I know, since I urge that the highest cerebral centres (the "organ of mind" or anatomical substrata of consciousness) represent parts of the body as certainly as that of the lumbar enlargement does; they are evolved out of lower centres, which, as everybody admits, do represent parts of the body. No one denies that the highest centres contain sensory elements; no one denies that very many, if not all, parts of the body are represented sensorily in the "organ of mind." But to their representation motorily in that organ there seems to be great objection. It is not

many years since the ascription of motor representation to any part of the cerebrum proper was denied. It is agreed upon now that some convolutions (Rolandic region) contain motor elements—and, according to some, nothing else. The præ-frontal lobes (convolutions in front of the Rolandic region) are said to be, or to be part of, the "mental centres." I admit that they are a great division of these "mental centres," but say that they are motor too—that they are the highest motor centres. And Ferrier, who agrees with me in thinking that these lobes are motor, finds that, after their ablation in monkeys, there is degeneration of fibres "descending" as low as the medulla oblongata, but no lower; this is proof positive that the præ-frontal lobes are, at least to some extent, motor. I will here state in outline what I believe to be the hierarchy of the motor centres, only alluding to that of the sensory series and ignoring the cerebellum.

1. The anterior spinal horns and their homologues higher up (nuclei of motor cranial nerves) are the lowest motor centres (both of the cerebral and cerebellar systems). These lowest motor centres, with the corresponding sensory centres, make up the lowest level of evolution of the central nervous system.

2. The convolutions of the Rolandic region are the middle motor centres of the cerebral system. With the corresponding sensory centres they make up the second or middle level of the central nervous system.

3. The præ-frontal lobes are the highest motor centres of the cerebral system. With the corresponding sensory centres they make up the third or highest level of the central nervous system, that is, "the organ of mind."

Here I may best remark on the differences between muscles and movements, a matter of vast importance. To speak figuratively, the central nervous system knows nothing of muscles, it only knows movements. I have already stated the speculation that all muscles of the skeleton are represented in the cerebrum in one set of movements, and all in the cerebellum in another set. I here give another illustration simplifying it in several ways. There are, we shall say, thirty muscles of the hand; these are represented in the nervous centres in thousands of different combinations—that is, as very many movements; it is just as many chords, musical expressions, and tunes can be made out of a few notes. I now speak of the representation of the muscles of the hand in the three orders of motor centres just spoken of. 1. In some lowest motor centres (anterior horns) which are evolved out of the muscles of the hand, these muscles are represented in numerous different combinations, as simple and very general movements. 2. In the middle motor centres (Rolandic region) which are evolved out of the lowest motor centres, the same muscles are represented (re-represented) in still more numerous different combinations, as complex and special movements. 3. In the highest motor centres (præ-frontal lobes), which are evolved out of the middle motor centres, the same muscles are represented (re-re-represented) in innumerable different combinations, as most complex and most special movements. Anticipating in part what is to come, the last representation is of "finest" movements of the hands in the anatomical substrata of tactual ideas and of other mental states.

I fear the doctrine of sensori-motor constitution of the "mental centres" will be a hard one to many of my medical brethren. My contention, nevertheless, is that the highest centres ("organ of mind") have no other function than that of representing or co-ordinating parts of the body; bearing in mind the subordinate centres, we may say that they represent parts of the body triply indirectly. Function is a physiological term, and it is, I submit, improper to speak of states of consciousness as being "functions of the brain;" we can only say that states of consciousness attend functioning of the brain, of those parts of it, at least, which are the highest cerebral centres. We can only affirm concomitance, and why immaterial processes always go along with the material processes of our brain is, as yet at any rate, inexplicable. The late Professor Clifford wrote:[1] "I may very well say that among the physical facts which go along at the same time with mental facts, there are forces at work. That is perfectly true, but the two things are on utterly different platforms, the physical facts go along by themselves, and the mental facts go along by themselves. There is a parallelism between them, but no interference of one with the other."

It is neither more nor less easy to understand the nature of the relation of the two utterly different and yet concomitant things if the physical thing, the "organ of mind," has a sensori-motor constitution, than it is on any other hypothesis as to the constitution of that organ. Here is an express repudiation of any intention on my part to attempt to explain psychical states by anatomico-physiological states. It is not the mind, but the physical basis of mind, which is a product of evolution; it is the organ of mind, not the mind, which, being an evolution out of the rest of the body, is representative of it. When tracing an evolutionary ascent from the muscles of the hand to the highest cerebral centres nothing was said even remotely implying that the most complex, etc., representation of these muscles became, or became part of, tactual ideas; it was only said that this most complex, etc., representation was part of the physical basis of those ideas. I know of no evolutionist of repute who has attempted the marvellous feat of "getting the mind out of the body." For my part, I am content with "getting" the organ of mind out of the rest of the body.

I contend that the highest centres represent all parts of the body, literally all parts supplied by nerves—not only sensory regions and muscles of such parts as eyes and hands ("organs of special sense"), but of legs and arms, of internal viscera, of external viscera (as sweat-glands), and all the rest. Under the head of movements, one takes in effects produced in glands by what the physiologist calls their motor nerves, and also negative movements, so to call them, that is, effects on musculatures produced through the intermediation of inhibitory nerves. The highest centres are centres of universal representation or co-ordination. When dealing with the physical condition in coma, Dr. Mercier writes: "Thus we arrive at this most important conclusion: that the highest nervous processes, which form the substrata of the most elaborate mental operations, represent at the same time not only the most elaborate forms of conduct and muscular movements, but also *every part of the organism* [italics in original] in some degree.[2] Ribot, in his remarkable and most valuable (work on "Personality," writes: "Nous pourrons dire que la couche corticale représente toutes les formes de l'activité nerveuse; viscérale, musculaire, tactile, visuelle, significatrice."

No one doubts that the lowest level of evolution (roughly, pons, medulla, and cord) represents all parts of the body; it is certain that motor effects in nearly all parts of the body are produced by discharges of the so-called "motor region" (motor division of the middle level). I am only going a step further when I suggest that the highest level (although "I for mind" in the sense of being the physical basis of mind) is also universally representing. A higher level of evolution is, so to put it, the lower "raised to a higher power." Each of the levels being universally representing their evolutionary differences are in the degree of complexity, etc., in which each represents all parts of the body.

The phenomena of an ordinary epileptic fit, epilepsy proper (I am not speaking of epileptiform seizures, which are owing to sudden discharges beginning in parts of the mid-cortical convolutions, or, as I call them, middle motor centres), seem to me to accord with the hypothesis of sensori-motor constitution of the highest centres and of their universality of representation.[3] Cessation of

[1] Fortnightly Review, December, 1874, p. 728.
[2] Brain, January, 1887.
[3] I have considered in detail the phenomena of epileptiform paroxysms with reference to the hypothesis of universal representations by the highest cerebral centres in the Bowman Lecture, Trans. Oph. Soc., vol. vi.

consciousness being the first, or a very early, psychical event in the paroxysm, I presume that the first correlative physical event must be a discharge (here a sudden and excessive one), beginning in some part of the physical basis of consciousness (highest centres). Now, it is certain that in a severe epileptic fit there are effects produced in nearly all, presumably in all, parts of the body, and obviously the effects we see are motor or their equivalents. In a slight fit of epilepsy (*le petit mal*), the effects are widely distributed; they are so various as pallor of face, increase of saliva, arrest of respiration, and emission of urine. The effects are crude, but this does not invalidate them as witnesses to the representation of parts of the body in the highest cerebral centres; the process by which they are produced is a crude one; the "epileptic discharge" differs from normal discharges in being sudden, excessive, and rapid; and also, I submit, in starting in some small part of the highest centres (a "discharging lesion" or physiological fulminate").

That artificially induced discharges of parts of the Rolandic region (middle motor centres of the cerebral system) produce effects in nearly all parts of the body, visceral included, is demonstrable. No one doubts that in this region all the skeletal muscles are represented in movements; but the organic parts also, presumably all of them, are represented in it. If curara be given to a dog, its skeletal muscles are, by paralysis of their motor nerve-endings, put out of reach of the effects of central discharges; upon Faradic excitation of the curarized animal's sigmoid gyrus (artificial respiration being kept up) the fit is limited to the organic parts; we witness effects on viscera or their apparatus which we can never observe in man; the dog's abdomen having been opened, there are seen, among other effects, increased flow of bile, a little paling of the kidneys, and contraction of the spleen. In this case the artificial discharge is started in part of the middle motor centres; but, at any rate, that universal effects are so produced gives some countenance to the supposition that the convolutions in front of these centres, highest motor centres, are also universally representing.

Another way of stating the function of the highest cerebral centres, is to say that while a man is having states of consciousness (in artificial analysis, Willing, Remembering, Reasoning, and Feeling), there are occurring correlatively with those purely psychical states the physical things, slight discharges of nervous arrangements of his highest centres representing the whole of his body. In differing states of consciousness different nervous arrangements of these centres representing or co-ordinating different particular parts of his body more than all the rest will be engaged.

It is just here that the harmony of psychology with the anatomy and physiology of the nervous system is, I think, to be best seen; it is here, too, that the basis for the comparative study of cases of insanity (diseases of the highest centres) with diseases of lower centres is established. I have elsewhere[1] analyzed very briefly, and, I admit, very imperfectly, the highest cerebral centres considered as they form the physical basis of consciousness.[2] The conclusion from that analysis was that the highest cerebral centres are sensori-motor arrangements representing all parts of the organism in most complex, etc., ways—a conclusion agreeing with the hypothesis of evolution, and strictly according with the phenomena of epileptic paroxysms. If that analysis be valid, there is no difficulty in seeing how it is that epilepsy proper is a disease of the "organ of mind." The epileptic convulsion is a brutal development of the most complex, etc., movements represented in the anatomical substrata of the four "faculties" mentioned, along with a development of the less complex, etc., movements represented by the middle and lowest motor centres.

I will here analyze the physical basis of but one mental state, artificializing largely. There is no such thing as a separate centre for tactual ideas, but for simplicity of exposition, we may imagine some part of the highest centres to be such a centre; popularly, it is a centre for objects explored by the hands. When we actually explore an object the skin of our fingers and the muscles of our hands are engaged; and at the same time all sensory centres from lowest to highest, and all motor centres from highest to lowest. The tactual centre represents the skin and muscles of the part of the periphery mentioned—is sensori-motor in that way. The sensory element in the tactual centre corresponds to the surface of objects (the homologue of color in visual perceptions and ideas), the motor element to their extension (shape and size). I have already mentioned the motor element when speaking of the hierarchy of motor centres. I illustrated by the representation of the muscles of the hand; their final representation (re-re-representation) in the highest centres is the motor element in the tactual centre.

During the actual exploration of an object there is a vivid mental state; we may call it a tactual perception. Now suppose we think of the object when it is absent, popularly, "have an idea of it;" there is then a faint mental state, a tactual idea. In both cases the centre for tactual ideas is engaged; a tactual idea is a faint tactual perception, and a tactual perception is a vivid tactual idea; the centre for tactual ideation and for tactual perception is one; it is made up of the same sensori-motor arrangements of the highest centres.

But it may be said that while thinking of the object there is no movement, and it may be averred that the correlative physical process is sensory only; but the sensory element corresponds only to surface; the extension requires accounting for; the object thought of has shape and size. I submit that there is corresponding to extension slight discharge of the motor nervous arrangements of the tactual centre, which, when strongly discharged in the actual exploration, did move the hand; there is "nascent movement." The physical difference more fully is that (1) during exploration of the object, having a tactual perception, the tactual centre is strongly discharged from the sensory periphery, and reacts upon the muscular periphery; there is strong and complete sensori-motor action, all orders of centres being engaged; while (2) during thinking of the object, having a tactual idea, the tactual centre is slightly discharged, and the discharge is limited to the centre; there is weak and incomplete sensori-motor action; the highest centres alone are engaged. In both cases there is sensori-motor action, in both the same nervous arrangements of the highest centres—those representing the skin of the fingers and the hand muscles—are discharged. So far for two degrees of normal discharges of the tactual centre. Now let us suppose that a sudden, excessive, and rapid discharge (such a discharge as that which produces an ordinary epileptic fit) begins in some part of the tactual centre, and soon involves the whole of it. We should then have a miniature epileptic fit. During the onset there would be tingling referred to the fingers; there would be (middle and lowest centres being subordinately engaged) also convulsion of the hand. No tactual ideas would arise during such a discharge.

Asking you to accept provisionally the conclusion that the anatomical substrata of will, memory, reason, and emotion (together states of consciousness), represent parts of the body (together, all parts of it, sensorily and motorily), in most complex, etc., ways, I go on to speak of the relevance of that hypothesis to the study of some important diseases. There is no difficulty in understanding that insanity arises from disease of the organ of mind. But we have to face this question. How is it that the superficially seeming quite different phenomena,

[1] Croonian Lectures, Journal, April 12, 1884.

[2] I then spoke of centres for will, memory, reason, and emotion, the artificially distinguished elements of consciousness. It was a mere artifice to imagine such centres. The evolutionist does not try to localize volition or any other mental faculty in the brain; he is content with attempting to localize parts of the body in the highest cerebral centres. For my part, I think there are not in the cortex cerebri any abruptly demarcated centres for any kind of representation. The recent researches of Beevor and Horsley on the mid-cortex seem to me to show that the current hypothesis as to localization is untenable.

1, convulsion with cessation of consciousness (an epileptic fit); and, 2, insanity results from morbid affection of the "organ of mind" (highest centres)? This problem is forced upon us. We cannot consider one of the two by itself, and ought not to try to explain each quite separately. For often enough there is the sequence, an epileptic convulsion with loss of consciousness, and then temporary insanity, for example, epileptic (post-epileptic, I think) mania. Moreover, I believe that paralysis also results from negative states of the highest centres; I submit that it exists in temporary post-epileptic insanities, indeed in every case of insanity.

After epileptic fits there is often insanity. There are two degrees of it; there is, according to the severity of the paroxysm, mania, or coma, physically two depths of dissolution effected by the prior epileptic discharge. I first take coma,[1] which is acute temporary dementia rapidly produced. Here I remark again on the need of distinguishing psychical states from nervous states. If any one compares and contrasts post-epileptic coma as a negative psychical state with a case of paralysis, say hemiplegia, which is a negative physical state, he is attempting a pseudo-comparative study. I submit that the negative affection of consciousness in the comatose patient implies a correlative negative state of more or less of his highest centres which causes paralysis. It is not the negative affection of consciousness, but the paralysis from the negative state of elements of the highest centres which that negative affection of consciousness implies, which we can reasonably compare and contrast with the hemiplegia. It is true that in post-epileptic coma there is not limited, regional paralysis, such as hemiplegia or monoplegia; there is supposed to be some universal, I do not mean total, paralysis. I am not speaking of paralysis of the muscles. There is loss of some movements of all parts of the body. That there is some universal paralysis after a severe epileptic fit accords with the hypothesis of universal representation by the highest centres, and is in harmony with the universality of the convulsion in the prior paroxysm. If a man cannot move an arm after a convulsion limited to that limb, no one hesitates to call that condition a paralytic one. Why then should not the name be given to universal motionlessness after a universal convulsion? To say that the patient who is unconscious does not move because he is unconscious is to give an explanation which explains nothing. Beevor has noted lateral deviation of the eyes after epileptic fits; surely this is indirect evidence of some paralysis. Moreover, Westphal, Gowers, and Beevor have observed alterations of "deep reflexes" after such seizures, and this too accords with the view that the man comatose after such seizures is paralyzed. Here let me say, once for all, that no doubt in post-epileptic coma, besides paralysis from loss of most complex movements represented in the highest centres, there will be after a severe fit some paralysis from loss of less complex movements represented in the middle motor centres, and some from loss of simplest movements represented in the lowest motor centres. For in the prior severe epileptic fit all centres are engaged; there is an excessive process from highest centres to muscles. Indeed (Westphal, Gowers, and Beevor), after some epileptic fits there is temporary loss of the knee-jerks, showing exhaustion of the lumbar centres, which are some of the lowest centres.

The conclusion about post-epileptic coma is very important, for from it we make the hypothesis that there is paralysis in all cases of insanity, a widespread or universal paralysis—that is, paralysis of a kind corresponding to the universality of representation of the body by the highest centres, which are certainly diseased in cases of insanity. I must now briefly analyze these cases of disease of the highest centres.

[1] I would refer all interested in the application of the doctrine of evolution to the investigation of diseases of the nervous system to Dr. Mercier's masterly article "Coma" (Brain, January, 1887), a most important contribution to the methodical study of insanity.

In cases of insanity the mental condition is, as Dr. Monro long ago insisted, duplex; it is of two opposite elements, one negative and one positive; cases of perfect dementia, if there be such a thing, where the mental condition is entirely negative, are excepted. Ignoring perfect dementia, there is always some negative affection of consciousness (negative mental symptoms) in cases of insanity; there are degrees from slightest defect of it, such as that existing in trifling confusion of thought, to nearly complete loss of it, as in dementia, or in coma, which is acute dementia. We must not speak as if there were no degrees between perfect consciousness and unconsciousness. There are also positive, often superpositive, mental symptoms coexisting with the negative. The defect of consciousness and the consciousness remaining (that is what I just called the positive mental symptoms) in cases of insanity vary inversely. When the positive mental symptoms are many and elaborate, and the defect of consciousness therefore little, the former may attract exclusive attention. Slight degrees of defect of consciousness are often disregarded. A patient may be said to be "perfectly conscious," and be said to have illusions, delusions, etc., as if these positive mental symptoms were his sole symptoms; but surely these positive symptoms of themselves imply the co-existing negative states of some non-recognition and some non-reasoning, that is, they really imply some co-existing defect of consciousness. A patient may be said to be "perfectly conscious," although, when his symptoms are given, he is described as apathetic, as forgetful, as confused, and as having lost regard for others; these popular statements are nearly, if not quite, equivalent to the technical statements that the patient is defective in will, memory, reason, and motion —in other words, that he *is* defectively conscious.

The correlative physical condition of the highest centres in cases of insanity is correspondingly duplex. The negative affection of consciousness implies a negative state of, or of elements of, some nervous arrangements (temporary loss of their function or actual loss of them) of the highest centres. It is this negative state alone which implies paralysis; this alone is dissolution, this alone is the result of disease in the sense of pathological change.

Now for the physical condition corresponding to the positive mental symptoms. As before said, when speaking of the case of paralysis of an external rectus and of cases of insanity, every nervous disease is to be considered as a flaw in an evolutionary whole; and the assertion was then made that great parts of symptomatologies are owing to activities of healthy nervous arrangements. I submit that all the positive mental symptoms in the symptomatology of insanities occur during activities of healthy nervous arrangements remaining in the maimed highest centres; they are, or are parts of, the insane man's mentation; they are, or are signs of, his lowered consciousness; his illusions, as we call them, are his perceptions, and his mental symptoms altogether are lower homologues of his normal mentation, and are his will, memory, reason, and emotion. Putting the matter still otherwise, the positive mental symptoms do not signify dissolution; they signify evolution going on in what disease has spared; they are signs of survival of the fittest states on the lower, but now the highest, level of evolution remaining. The sensori-motor arrangements of this lower level (sub-level of the highest level) may be over-active from loss of control, but this is a physiological abnormality; when I say that they are healthy, I mean that they are untouched by any pathological process; they are in the same case as the heart is when it is beating more frequently after section of the vagus. When a general paralytic believes himself to be Emperor of Europe, I submit that this delusion does not arise during activities of any nervous elements touched by any sort of pathological process; but, on the contrary, that it is framed during activities in what remains of his highest centres, that is to say, in what disease has spared—presumably the posterior lobes and what is left intact of

the anterior. This delusion (his belief) signifies evolution going on in the remains of a mutilated nervous system, as certainly as his beliefs when sane signified evolution going on in an entire nervous system.

I can now consider the other degree of post-epileptic insanity, mania. Manifestly the mental condition is duplex; the patient is "unconscious" (significant of dissolution) as well as furiously acting (evolution going on). By artifice, speaking of layers (sub-levels) of the highest centres, I will suppose that his "unconsciousness" signifies loss of function of the highest two layers of his highest centres. This produces some universal or widespread paralysis, but less than that in post-epileptic coma, in which, a deeper dissolution, we shall imagine that the highest four layers are functionless. But the positive symptoms of the post-epileptic (unconscious and) maniacal patient are owing to over-activity of sensori-motor arrangements of the healthy third layer and of still lower layers of his highest centres; these layers, now his highest, are in great hyperphysiological activity, being uncontrolled by the normal highest two layers which have been suddenly rendered functionless. To say that there is some universal paralysis and yet universal activity is not contradictory. It would be a flat contradiction if it were said that all the patient's muscles were perfectly paralyzed and at the same time in great activity. There is supposed to be loss of some movements of all muscles, with overdevelopment of other movements of those same muscles. Let me consider the matter analogically. Often do we encounter cases of imperfect hemiplegia; here, although clinically we may say that the muscles of the limbs are weak, there is really loss of some movements of all the muscles of the limbs, with persistence of others of those same muscles. I can now consider the sensori-motor constitution of the nervous system more widely.

In order to make a proper comparative study of nervous diseases on a large scale we must reduce different symptoms to a common denomination. The widest assertion in accord with the hypothesis of sensori-motor constitution of the whole nervous system is, that negative lesions of every part of it produce paralysis, sensory or motor, or both, and nothing whatever else.

I will illustrate this dictum further, speaking, however, of motor paralysis only, by which I always mean loss of movements. The assertion made is not a mere truism. For instance, it may be said that negative lesions of the highest cerebral centres cause loss of consciousness. I have been urging that they produce paralysis. I admit that consciousness ceases or diminishes correlatively with loss of function in these centres; but this is not contradictory of the statement that the loss of function causes paralysis. So anxious am I to make out a good case for the sensori-motor constitution of the highest centres that I will state a comparatively simple example of artificially produced insanity, dementia, in a lower animal. When a rabbit's cerebrum is cut out the animal is demented. But movements of every part of its body can be evoked by appropriate incitations. Nevertheless, I declare that the animal is paralyzed. It retains all simple movements represented on the lowest level of evolution, which is pretty much all that is left of its cerebral series. But I submit that it has lost all the more complex movements; all those it no longer makes—all those movements which, in the human subject, we should distinguish as the physical aspect of conduct—and is, therefore, universally paralyzed. Further illustrations must be given in outline and briefly. We ought to analyze symptomatologies very carefully; the positive or super-positive symptoms in any case of negative lesion of any nervous centre cannot possibly result directly from that lesion. For example, the destruction effected by a tumor of the middle lobe of the cerebellum cannot produce the disorder of co-ordination which nevertheless is present in such a case. My submission s that this lesion produces paralysis only; this is first, I think, loss of some movements of the spinal muscles. The positive symptoms, the erratic movements of the legs by which the patient in an early stage of his ailment does somehow get along, are the outcome of over-activity of perfectly healthy nervous arrangements; these are doing more than their normal share of work. So that, comparing and contrasting such a case with one of hemiplegia, the things comparable and contrastable are not the "disorder of co-ordination of locomotor movements" with the hemiplegia; the comparison and contrast are of two cases of paralysis, of loss of movements of the spinal muscles with loss of movements of the limbs. I submit that the formula describing all inco-ordinations with negative lesions of nervous centres is that there is, negatively, loss of some movements, paralysis (this alone being the result of pathological change), with, positively, forcing of some other movements of the same muscles. In saying this, the assertion I made early in this address, and repeated when stating the duplex condition in cases of insanity—that much of the symptomatologies of nervous diseases is owing to activities or over-activities of healthy nervous elements—is implicitly reiterated. Now for other examples of paralysis from negative lesions of centres.

I believe that in what is commonly called tremor in a case of disseminated sclerosis, say of an arm, there is paralysis in the sense of loss of some movements of the limb; the tremor itself is owing to the fact that the excursions of the limb have to be effected by fewer, and presumably less fit, movements than normal. Observe there is loss of some and retention of other movements of the same muscles. The movements by which the limb does carry, although erratically, a cup to the mouth are not blameworthy; they are the best in the evil circumstances, the next best to the normal; they are produced, I suggest, by discharges of healthy nervous arrangements. Let me illustrate the principle involved by a very simple case, and this time by one in which the muscles are paralyzed. When a man has paralysis of the extensors of the forearm, his grasp is weak and the hand moves clumsily in all its uses. But no one thinks of blaming the flexors for the weak grasp and for the clumsy operations of the limb; the flexors are acting faithfully; what they do is badly done because the extensors will not co-operate. So I suggest that in the kind of tremor spoken of, the fault is that certain movements being lost they no longer co-operate with others which, being unaided, move the limb erratically; the real fault, what the pathological change causes, is paralysis. That a patch of sclerosis, if it be an absence of proper nervous elements, can cause any movements, good or bad, is an impossible thing; the tremor has, however, been ascribed to imperfect function of intact axis-cylinders in the parts sclerosed. Now for another example. I have long held that the lesion in cases of aphasia produces paralysis in the sense of loss of complex, etc., movements of the articulatory muscles. It may, however, be urged that the articulatory muscles move well; so they do in simple operations, but they never move so as to make articulations (syllables). I have so recently dealt with this matter[1] that I will say no more of it. I will, however, allude to what I said of Semon and Horsley's experiments on the representation of the vocal cords in the cortex. These experiments demonstrate that in one case at least there may be loss of some movements of a muscular region, with persistence of so many other movements of that region that no disability in the working of the muscles is discoverable. (These experiments are a strong confirmation of Broadbent's well-known hypothesis, for one case at least.) There are other cases in which paralysis exists in which it is not expressly thought of. In cases of pernicious diabetes the lesion is supposed to be of a certain part of the great vaso-motor centre; if so, then what the disease (pathological process) produces is nothing but paralysis of the hepatic arterioles. Speaking figuratively, the medulla oblongata knows nothing of glycogen or sugar; it only

[1] British Medical Journal, July 14 and 21, 1888.

knows the hepatic arterioles. Thus, in a scientific classification, pernicious diabetes is a paralysis from lesion of a part of the spinal system (lowest level of evolution of the central nervous system) as certainly as that ordinary progressive muscular atrophy, or anterior-polio-myelitis, is. I suggest that the xerostomia ("dry mouth"), first described by Hutchinson, and soon afterward by Hadden, is also a paralysis—that it is owing to a negative lesion of the centres for the motor nerves of the salivary and other oral glands.

I submit that the essential thing, that which disease, in the strict sense of pathological change, produces, in cases of insanity, "disorders of co-ordination" with negative lesions, tremor, aphasia, pernicious diabetes, and xerostomia is paralysis. This way of looking at cases is most important when we are engaged in the comparative study of nervous diseases, and especially of insanities (diseases of the highest level) with diseases of the lowest level.

I will now give a series of fragmentary illustrations, largely hypothetical, of losses of some and persistence of other movements of the same muscles, the movements lost and those persisting varying according to the level of evolution damaged. I submit the hypothesis that (1) progressive muscular atrophy, (2) paralysis agitans, and (3) general paralysis are homologous diseases. The comparison and contrast is not of wasting of muscles, tremor, and a negative psychical defect. Analysis shows, I think, that, artificially limiting illustration to the hand, there is loss respectively of (1) simplest, (2) more complex, and (3) most complex movements of the hands. The comparison is of three cases of paralysis. The lesion is supposed to be wasting of cells, in the order from smallest toward largest, of lowest, middle, and highest motor centres respectively. The cases differ according to the level of evolution morbidly affected. Referring back to what was said on the hierarchy of motor centres, I now go into more detail.

1. In progressive muscular atrophy there is loss of simplest movements of the hands (cerebral and cerebellar), of those represented in some of the lowest motor centres (anterior horns). In this case the muscles are cut off from the influence of the whole central nervous system and waste. It is important to note that there is retention of more complex (middle centres) and most complex (highest centres) movements of the hands, certainly of motor nervous arrangements for them. Did not motor nervous arrangements still representing the hand remain in the highest centres the patient could neither think nor dream of moving the part, and would have no physical basis for tactual ideas.

2. In paralysis agitans there is (this is, of course, hypothetical) loss of more complex movements of the hand, those represented in the middle motor centres. There is retention of the most complex movements represented in the highest motor centres, and also of the simplest represented in some lowest. With this loss of more complex movements (we might say "middle movements") there is, in the tremor, development of simplest movements of the same muscles, the latest stage being rigidity. I submit that these movements are the result of mere physiological over-activity of the healthy lowest motor centres. To repeat, there is a duplex condition of the hand; negatively loss of complex (middle) movements of its muscles, and, at the same time, super-positively, over-development of simplest (lowest) movements of the same muscles. This case (2) differs doubly from (1), for in (1) the movements lost are (*a*) simplest, and (*b*) both the cerebrum and cerebellum are cut off from the muscles, while in (2) the movements lost are (*a*) more complex, and (*b*) the cerebellum remains united through the lowest motor centres with the muscles. (I have suggested that the cerebellum co-operates with the anterior horns in producing the tremor.)

3. In general paralysis there is loss of some of the most complex ("finest") movements of the hands, those represented in the highest motor centres, of those entering into the physical bases of tactual ideas and of other mental states. Here there is retention of less complex (middle) and of simplest (lowest) movements.[1]

Of course the negative psychical defect in general paralysis is wider than that answering to loss of motor elements in the highest centres representing the hand. I have been artificially limiting the illustration. Yet if Spencer be right in saying that all other ideas have to be translated into tactual ideas, to lose tactual ideas is to become imbecile. I will here make further remarks on the negative mental defect in cases of general paralysis. I ask you to bear in mind the suggestion that the positive mental symptoms in this insanity, as in all other insanities, correspond to activities of healthy nervous arrangements; if so, we have nothing to do with them at the time when we are dealing with the effects of pathological processes.

Most mentation is carried on in visual and tactual ideas, and by aid of words. To have negative affection of consciousness is therefore to have especially loss of these three—I shall limit consideration to them—and thus it implies that there is correlatively a negative state of their sensori-motor bases. In general paralysis the lesion, if of the highest motor centres, is of the motor elements in those sensori-motor nervous arrangements—is loss of more or fewer of the most complex ocular, manual, and articulatory movements; the lesion therefore produces paralysis in the sense of loss of "finest" movements of the three parts. I submit that, taking an early stage of general paralysis, the tremor of the hands is indirect evidence of loss of most complex movements of these parts, and further evidence is the lack of dexterity in manipulation. Similarly for the defective articulation. Now for paralysis corresponding to loss of visual ideas; in these ideas most of all mentation is carried on. Here I admit a discrepancy. It is said that there are no abnormalities in ocular movements in general paralysis; but I think that there is, in some cases, a want of even gliding of the eyes in their different excursions. I say this diffidently, and, instead of founding anything on it, will admit that I can show no evidence of paralysis answering to loss of motor elements of the physical bases of visual ideas in cases of general paralysis.

## DETAIL IN SURGERY.

### Being the Address in Surgery, Delivered Before the British Medical Association.

By T. PRIDGIN TEALE, M.A., F.R.C.S., F.R.S.

In deciding what line of thought to select for this address, I had to consider whether, following the example of many of my predecessors and of the earlier retrospective addresses, to give an account of recent advances and changes in surgery, or to select some definite subject perhaps not entirely in accordance with precedent.

Happily, my immediate predecessor devoted his address to a review of the surgery of the last half century, absolving me from the obligation to adopt a similar course, and setting me free to choose a subject more congenial to my habit and work.

"Detail in Surgery" is the title selected for this address, in which I hope to show how much some of the triumphs and shortcomings of modern surgery are made or marred by the carrying out of detail, detail which is essentially embodiment of principle, not the mere multiplication of points of practice such as may not materially further the end in view.

In working out this line of thought, I hope to be able profitably to employ the time at my disposal, and to give

[1] Of course I do not mean that the lesions in general paralysis are limited to the highest motor centres. I am dealing with what I suppose to be the effects of lesions of those centres in this disease, and am taking but one fragment of these effects in illustration. Moreover, general paralysis is not a well-defined clinical entity.

prominence to conclusions which have been formed during a surgical life of over thirty years, made up not of my own work alone, but very largely of the freest interchange of thought and experience with most friendly and active-minded colleagues, medical and surgical, with whom it has been my great happiness to be associated. In so doing, it has been my endeavor to be as little egotistical as is compatible with the attainment of the end in view.

*Ligature of Arteries.*—It happened not long ago that I had to deal with a wound of the brachial, at the bend of the elbow. Esmarch's tourniquet enabled me to expose beautifully to the eye a longitudinal slit in the artery. Of course I was obliged to apply a ligature on both sides of the puncture. There were then clearly exposed to view the two ligatures, and about half an inch of the artery containing the slit. It occurred to me to divide the artery between the ligatures, and so to relieve obvious tension. I then appreciated what I had never before fully realized in connection with ligature of an artery, the immense elasticity of the arterial coats. The separated ends receded fully half an inch from one another. The question at once occurred to me, Can it be right ever to tie an artery by a single ligature, and to leave this powerful force of elasticity to work for ulceration of the coats and gaping of the ulcer, with the risk of final disturbance by retraction of the divided ends when ulceration has completed its work? May we not here find an explanation of the numerous failures of ligature of the great arteries of twenty and thirty years ago, and of the fatal secondary hemorrhages, chiefly from the distal end? Some may say that antiseptics and the cutting short of the ligature have changed all that, have reduced the risk of ulceration of the coats of the artery and of secondary hemorrhage. Well, antiseptics fail now and then; and if they should fail we may be thankful for the additional protection of a doubly-tied divided artery. Secondary hemorrhage and fatal result will be thereby rendered extremely improbable. Recently I assisted my friend, Mr. R. N. Hartley, in a case in which he first ligatured the femoral and, a week later, the external iliac on the same side in the same patient. On both occasions he doubly tied and divided the artery with admirable result. This principle, proposed by Abernethy and afterward forgotten, has recently been restored to practice at St. Bartholomew's Hospital by Mr. Walsham, and is, I believe, practised elsewhere. May we not call this "a detail" in the operation of tying an artery? Does it not embody a principle—the principle of physiological rest? Are we to recognize and act upon the fact of the elasticity of an artery or are we to ignore it, and to place our patient at the mercy of elastic drag, tension, ulceration, retraction when liberated, and secondary hemorrhage? Does it not also involve the larger principle of *rest* as an important factor in the healing of any tissue.

*Stricture.*—There is a form of instrument for the treatment of stricture which has been but little written about, and although at last slowly making its way into use, has not met with the attention which I feel sure it deserves. It is known to me by the name of "Lister's sound," and was invented by Sir Joseph Lister.

From the very commencement of my professional life I have been familiar with and have been taught to use in the treatment of stricture "bulbed" steel sounds, which seem to have existed as traditional instruments in the Leeds Infirmary, were constantly used by my father and the older surgeons, and were, I believe brought to Leeds by the late Mr. Samuel Smith, who had learnt their use from his master, Sir Charles Bell, in Edinburgh. The virtue of the bulb is this: that, the stem of the instrument being necessarily smaller than the bulb, as soon as the bulb has passed through the stricture the instrument is free, and the touch of the surgeon is at liberty to perceive the character of the succeeding part of the urethra. Compared with the bulbed sound, the ordinary catheter, which, as a student, I frequently witnessed in use in the treatment of stricture, was clumsy and eminently unsatisfactory. The defect of the bulbed sound, in common with most other methods of treating stricture, was, that as soon as one size had been passed through a stricture, the same process of difficulty had to be encountered in passing the size larger. Some twelve years ago, while I was considering how to overcome this difficulty, our house-surgeon, Mr. Rowell, on his return from a visit to Edinburgh said to me: "Here is the instrument you want, a Lister's sound." I ordered a set, and I have used them ever since, exclusively, and have never flinched one moment from my allegiance to them. The principle of the instrument is this. It is bulbed at the point, like our old bulbed sounds: Then after the narrow neck the stem gradually increases until it attains, at a point about four inches from the bulb, a calibre two sizes larger than the bulb. Thus: No. 1 at the bulb swells to No. 3 or 4; No. 9 to 12; No. 11 to 14. It is clear, then, that if you can once pass No. 1 safely into the bladder you have prepared the way by the thickness of the stem for the more easy introduction of a sound with a bulb of the size of No. 2, and so on, each number passed rendering the way more easy for its successor. As a matter of fact, the larger sizes are passed with constantly increasing facility.

Have we not here a "detail" in the form of an instrument which solves many difficulties, combining the advantages of the bulbed sound with those of the conical sounds and bougies, and avoiding the disadvantages of both? It destroys the need of catheters with the hollow eye capable of carrying concealed poison, of gum-elastic catheters, and catgut bougies with the possibility of septic material lurking in interstices and cracks, and reduces very greatly the need of perineal section or internal urethrotomy.

Let me sum up my own experiences of the use of Lister's sound, which for the last twelve years has been, both in hospital and private practice, most satisfactory. Since their adoption, as far as I can recollect, I have only once had to perform perineal section from inability to get through, or to satisfactorily dilate a stricture. I have never performed internal urethrotomy, nor felt the need of it. Rigors are extremely rare after the use of Lister's sounds. This rarity of rigor I am inclined to attribute to the fact that in nearly every instance dilatation has been carried, at the first sitting, up to 10, 11, or 12. It is my belief that full dilatation at the first sitting is safer than the older method of partial and gradual dilatation, and for this reason: Even in partial dilatation there is frequently some laceration or bruising of the surface at the strictured point. If the stricture be only partially dilated, there remains a narrowing at this sore point sufficient to materially arrest the flow of urine, and therefore there is urinary pressure on the raw surface; whereas in full dilatation the urine flows along the urethra equably and without undue pressure at any point; and puts no stress upon the tender and perhaps lacerated surface of the stricture.

In a small number of cases I have failed to introduce Lister's No. 1, but these have been got over by the aid of Teevan's filiform guide, which in every case was successfully passed. The guide having been introduced through the stricture, its outer end is then screwed into the tip of a conical sound, like Lister's, with the bulb cut off. The filiform bougie guides the solid instrument through the stricture, and thus dilatation up to 4 or 5 Lister is secured, with the usual easy sequence up to 12 or 14.

*Effective drainage* may be defined as "such a provision for the escape of fluid from any cavity as shall secure that the discharges, which when secreted are sweet, shall escape from the cavity before they have time to putrefy, and shall be received into one of the aseptic absorbent materials with which surgery is now so abundantly provided." Formerly the idea of drainage was almost limited to "free incision and a dependent opening." This idea was true to a certain extent and in some cases, of which the following is a brilliant example: A man was received

into the Leeds Infirmary suffering from pneumothorax on the left side, from broken rib. The air was rapidly absorbed, but shortly the pleural cavity became full of fluid. This was drawn off twice, and on the second occasion was purulent. For some reason or other, the patient being extremely ill, an opening was made into the chest in front. He continued to lose strength and flesh, became extremely emaciated and albuminuric. As a forlorn hope, an incision was made into the pleural cavity posteriorly, whereby a free, dependent, self-draining opening was secured. In three months the wounds had healed, the patient had gained forty-two pounds in weight, had lost his albuminuria, and was well.

But a dependent opening is not always the most efficient or the best. I was requested by my colleague, Mr. Mayo Robson, to see with him a lady with pelvic suppuration discharging through the rectum, that is, by a dependent opening. It was the source of much pain and of occasional febrile attacks and ill-health. A tumor about the size of an orange, and supposed to be the source of the pus, was felt by rectum and vagina. Mr. Robson carried out the following treatment, agreed upon at our consultation: Having exposed the tumor by direct abdominal incision, he stitched the peritoneum of the edge of the incision to the upper surface of the tumor, leaving a small area of the tumor exposed, and rendered thereby extra-peritoneal. He then cut into the tumor until he reached a collection of offensive pus, and washed out and drained the cavity. Immediately pus ceased to appear by rectum, that is, by the downward drainage, and in four weeks the whole was healed and the patient was well.

Until recently surgery has been too much a slave to the principle of a dependent opening. A dependent opening may be for the moment efficient while the cavity is distended, and yet, after it is emptied and collapsed, may become valvular and inefficient. Moreover, when a large cavity has been emptied, the walls may, by their collapse, shut off portions of the surface from satisfactory drainage. Drainage, therefore, is a "detail" which needs to be studied in reference to each individual case. The leading idea should be so to provide, whether by position of openings, by shape of opening, or by use of drainage-tube, that secretions shall escape from every part before they have time to become septic, remembering that if a way of escape for fluid without risk of imprisonment be provided, we generally have to aid us the elasticity, or contractility, or displacing compression of surrounding tissues, and that we may be, to a great extent, independent of mere gravitation.

Such ideas, clearly held, will set us free, and encourage us to continue, as we now do, to drain abdominal cavities, abscesses, irremovable cysts, distended gall-bladders, pelvic abscesses, and, perhaps, even abscesses connected with diseased hip-joint, by a mode of drainage which is anything but a dependent opening, but which we have learnt how to render efficient.

This idea of drainage, combined with the principle of rendering a cavity extra-peritoneal, is the key to some of the recent masterly developments of abdominal surgery, whereby deeply seated cavities containing offensive and septic materials can be treated with comparative safety.

*Peritoneal Stitching.*—Another detail in surgery which I have only recently learned to appreciate is that of the independent stitching of the peritoneum. The looseness of the attachment of the peritoneum to the abdominal wall allows it to be dealt with with great freedom, as has already been referred to in the paragraph on "Drainage." A few months ago, when I was about to stitch up the abdominal wall after ovariotomy, Mr. Hartley, who was assisting me, asked, Why not stitch up the peritoneum alone, and then unite the rest of the abdominal wall by a separate set of stitches? I at once acted upon the suggestion, knowing that it had been practised by others. The effect was to make the closing of the abdominal wall much simpler, and not more tedious. The advantages appeared to be: (*a*) absence of tension on the peritoneal union, (*b*) very little bleeding from the peritoneal stitches, and (*c*) greater facility in uniting the abdominal wall, from not having to provide for the accurate adaptation of the peritoneal edges. After the operation the patient seemed to be more free than usual from discomfort in the wound. It is possible that further advantages may accrue, such as diminished proneness to hernia of the scar, and less liability to suppuration in the track of the sutures. So much for the value of this detail in ovariotomy and abdominal section. But the lesson thus learnt went further. Not long ago I was called in the middle of the night to a patient suffering from strangulated umbilical hernia, who had been admitted into the Leeds Infirmary in order that she might undergo an operation for radical cure, strangulation having suddenly set in while she was waiting for the operation. After reducing the bowel and removing a large mass of omentum, I was prepared to close the abdominal ring, which had a diameter of an inch. To close this in the ordinary way by sutures, so as to secure union of the peritoneal edge, which is adherent to the margin of the ring, is no easy nor certain proceeding. I therefore, with the scalpel, incised round the margin of the ring, and thereby got a starting-point whence I could strip the peritoneum from the under surface of the abdominal wall over a radius of about an inch. The edges of the opening in the peritoneum were then easily brought together, and closed by a row of five or six stitches. The peritoneal cavity having been thereby closed and cut off from the wound, two wire sutures were inserted into the aponeurotic ring of the linea alba, so as to bring the opposite sides together, and were cut off, to be left as a permanent barrier. It seems likely that such a proceeding may increase the safety of operations for umbilical hernia, whether undertaken to relieve strangulation, or for radical cure.

*The Sphincter Ani in the Surgery of the Rectum.*—There is a detail in operations on the rectum or anus which, rightly carried out, contributes very greatly to ease in operating, to the comfort of the patient after the operation, and to the permanency and perfection of the result. As a preliminary step, in every operation on the rectum or anus, there should be dilatation of the sphincter ani by the fingers. To some this may seem a truism, a self-evident proposition, which it were waste of time and breath to assert. The fact, however, is that it is far from self-evident to many surgical minds, and has not been acted upon as a general rule, and, until very recently, has been absolutely ignored by many rectal specialists, and by writers on general surgery.

First and most conspicuous in this relation are bleeding internal piles. Some twenty five years ago, I was asked to operate for bleeding piles on a gentleman about thirty years of age. On mentioning the case to my father, he said, "Dilate the sphincter, and most likely you will never have to operate on the piles; they will be cured." His anticipation proved to be correct. The advice was acted upon, and the gentleman has remained well to the present time. So late as in 1887 did M. Verneuil bring this subject as a novelty before a meeting of surgeons in Paris, nearly all of whom were entirely ignorant of the question. This experience was amply confirmed by subsequent cases, and I now rarely operate on internal hæmorrhoids without having previously tested the effect of simple stretching of the sphincter. In more severe cases, requiring the removal of hæmorrhoids, the stretching, as a preliminary to operation, at once displays the piles to view, and places them in a ready position for being seen, seized, and dealt with. Another advantage is that, after the operation, the parts remain at rest, and the wounded tissues are not liable to protrude and to be strangled by a resentful sphincter. Also, if there be bleeding, there is great facility for the escape and discovery of the blood, and therefore less danger of concealed hemorrhage, which may fill the rectum with a large clot, perhaps only to be suspected from the pallor and feeble pulse of the patient. A further advantage is that wounded and granulating sur-

faces within the rectum are not interfered with, or kept in a painful or irritable state, after the fashion of fissure, by an over-active, excitable sphincter. Two cases have recently been under my care in which long-continued suffering, after removal of piles without stretching of sphincter, was at once cured by simple dilatation.

Contrast with this the clumsy and unscientific plan, until recently recommended in the text-books, of requesting the patient to "bring down" the piles by sitting over hot water before operation, so as to afford the surgeon an opportunity of playing hide and seek with the elusive hæmorrhoids, aided by their confederate sphincter.

In operations for fistula in ano, dilatation of the sphincter is an essential preliminary. If the internal orifice be close to the anus, it is at once displayed or brought within easy reach. If it be at some distance, and beyond the sphincter, this proceeding renders it possible to cure the fistula without extending the incision up to the internal orifice, and so risking loss of control over the action of the bowel by too free division of the sphincter ani. Such deeply burrowing fistulas I have cured on several occasions in the following manner. The sphincter having been freely dilated, the external orifice of the fistula was enlarged laterally in such a way that the opening in the skin was the base of a triangle with its apex at the other end of the fistula, where it communicated with the bowel. The track of the fistula was freely scraped, and a drainage-tube was inserted, so as to reach within half an inch of the opening into the bowel. Undoubtedly the key to a successful result in such a case is the "detail" of dilatation of the sphincter, which by its relaxation allows the contents of the bowel to pass away easily, and without forcing secretions backward into the fistula, until time has been given for the freshly scraped surface to unite and seal the offending track. Time will not allow me to say much more on this far-reaching topic, but there is one point I must not omit. Of late years, the question of dilatation of the os and cervix uteri, and of treatment of the cavity of the uterus for endometritis and other metritic troubles, has come very much to the front. Indeed, it is a selected subject of discussion at the present meeting in the Obstetric Section. In some of the discussions by gynecologists I notice that much is said of constipation as a factor in these cases, and as one that ought to be treated and remedied, of course by medicines, as a preliminary to any special interference with the uterus. In some cases I know, and in many others I suspect, that the cause of the constipation is a tight, or spasmodic, or irritable sphincter. In such a case stretch the sphincter, and you may "throw physic to the dogs." And let me note in passing that there are instances in which the sphincter may cause constipation and its train of symptoms, without any evidence of fissure, or anal pain, or bleeding; or there may be what I have often observed, but have never seen described, a peculiar rigidity, a sort of inelastic ring, like a fibrous degeneration of the muscle, which does not resist the introduction of one finger, but bars the rectum as with a ring of iron to the introduction of two. In such cases only artificially softened evacuations can escape. May we not consider dilatation of the sphincter to be a "detail" in surgery worth study no less by the physician than by the surgeon?

*Ether versus Chloroform.*—This is a subject on which I wish to speak with a sense of grave responsibility—the more so that I have to express views which are strongly opposed to those uttered at Glasgow last year by my predecessor in this chair.

If anyone asks why I venture to differ so widely and strongly from one whose surgical experience is probably not less than my own, and may be greater, my plea is as follows:—

For the first fifteen years of my surgical life, which includes ten years as surgeon to the Leeds Infirmary, I knew little of any anæsthetic but chloroform. So far, probably, our experience runs parallel. During the last fifteen years ether has almost superseded chloroform in my practice. Here the parallel ceases. Sir George Macleod's second fifteen years are still devoted to chloroform. He cannot speak from fifteen years' experience of ether. As a result of the comparison of these two periods, I unhesitatingly assert that ether is, for safety to the patient and for comfort and convenience to the operator, immeasurably the better anæsthetic of the two. Ether can be given "*tute, cito, et jucunde!*" I say can be; would that I could say *is* always so given.

My earliest experience of ether was in the method introduced by Dr. Joy Jeffreys, when, at the International Ophthalmic Congress in 1872, he preached his crusade against the almost universal use of chloroform prevalent in the United Kingdom, and compelled British surgeons to take up the question of ether. He appealed to our sense of duty in reference to the fearfully increasing fatality of chloroform, and we responded to his call, in spite of the grave disadvantages of the clumsy, wasteful, nay harmful, method of giving ether, by lavishly pouring it into a cone formed of a towel, to which he introduced us. The disadvantages of ether so given were great and obvious. The struggling of the patient, the icy coldness of the inhaled air, the saturation of the air of the room by twelve, fifteen, or twenty ounces of ether spent upon a single case, and the not infrequent, and occasionally fatal, bronchitis which followed, were such obvious drawbacks that the wonder is that ether survived as an anæsthetic in England until it had time, by improved methods and increased experience, to win its way to the pre-eminent confidence which it now commands. The towel was, after a time, superseded by the wicker grid—brought over from America by a late chaplain to the Leeds Infirmary, the Rev. E. Spencer Gough—an improvement on the towel, but sharing with it the chilling of every inhalation by the evaporating ether as well as a high percentage of waste of the anæsthetic. The method of administering nitrous oxide gas before giving ether was, in his later years, largely given up by Clover. Next came the great step which was the saving of ether as a British anæsthetic. Ormsby, of Dublin, invented the inhaler in which the exhaled warm air, charged as it is with ether, was received into an india-rubber bag and breathed over and over again, thus economizing the heat of about ninety per cent. of the exhalations and reducing the waste of ether. This idea was taken up by Clover and developed into the present form of inhaler, which, as far as I know, is unapproached by any method of giving ether that has come into use. But, *Non cuivis homini contingit adire Corinthum.* It is not everyone who knows, and there are some who are incapable of learning, how to administer ether, even with Clover's inhaler.

There are many hospitals in England, and still more, I believe, in Scotland, where the use of ether is practically unknown, or where, if ether is given, the obsolete towel or the grid, or the very inferior inhaler of Ormsby is used; or even should the hospital possess a Clover, it may not possess an etherist who knows how to use it to the best advantage. To administer ether badly is to bring it down nearly to a level with chloroform as to safety, and to render it inferior to chloroform as to comfort to the patient. A bad etherist will cause fear, coughing, distressing sense of suffocation, excitement, struggling, blueness of lips, mucous rattling in the trachea and bronchi. He will take many minutes, five to ten, in getting his patient under the anæsthetic, will use twice or thrice as much ether as is needful, will keep his patient when unconscious overcharged with ether, in a state of profound stertor, and will now and then set up a dangerous bronchitis. A good etherist will win the confidence of his patient, even of the most timid, by judicious encouragement, and by first applying the mouthpiece alone. As confidence becomes established he adds the reservoir, and then the india-rubber bag, slowly turning on the ether as tolerance of the vapor becomes established, and unconsciousness begins to steal on. Then he more rapidly increases the proportion of ether, and the patient quickly falls into complete

anæsthesia. Such an administrator will, in nine cases out of ten, have his patient ready for operation in two or three minutes, and not infrequently in about a minute and a half, without a struggle, without coughing, often without even a transient sense of suffocation, and with the expenditure of about half an ounce of ether, and will need but about one ounce of ether for each quarter of an hour that the anæsthesia is kept up. In such a case we need fear no danger at the time, nor subsequent bronchitis. So much for the patient.

But there is another side of the ether question which I have never seen adequately stated. The advantages to the operator of using ether instead of chloroform are very great. In the first place, his anxiety is less, his fear of a fatal issue is less, and when obliged to trust to an inexperienced administrator, as he must do at times in sudden emergencies, he can more efficiently keep an eye on the patient's condition, and superintend the administrator, than when chloroform is used.

In the second place there is a saving of time, a patient being brought under the influence of ether in two or three minutes, whereas chloroform, in my experience, needs eight or ten. Such a saving is of no slight moment in modern hospital practice now that the sphere of surgery has become so enormously extended.

In the third place, under ether return of consciousness to pain generally lags behind the return of mental perception, and thus anæsthesia can easily be re-established without interrupting the operation. So marked is this fact toward the end of a prolonged operation that sometimes the surgeon may continue to operate for ten minutes or a quarter of an hour without re-application of the inhaler, and even converse with his patient while stitching up a wound. This is hardly, or rarely, the case with chloroform. Let anyone who is not yet a convert to ether, or who, having used ether, is wavering in his allegiance to it, ask himself these questions. Have I myself studied the details of successful etherization? Am I using the best form of inhaler? Have I taken pains to have those who act for me properly taught and trained? If not, let him ask himself one more question—Have I done my duty?

*Instruments—The Scalpel.*—An essay on "Detail in Surgery" would hardly be complete without some words about "instruments." Instruments bearing the same name are apt to vary in shape. Some forms are certainly better than "other some." Certain good forms and types are apt to go out of fashion, to "get out of print," and to be superseded by inferior types. It is often difficult to get the best type of instrument, or to renew a lost form, so great is the tendency to degeneration and departure from the original type. Take as an illustration one of the simplest and most frequently used, a "scalpel." How rare it is to meet with a scalpel of good form; and yet we have the pattern admirably drawn in the work on *Surgery*, by that master hand in the selection, designing, and handling of instruments, Sir William Fergusson.

The scalpel should be to the surgeon what the pencil is to the artist. The surgeon should be conscious, even with his eyes shut, where the point of his scalpel is, his eye should be upon the tissues he is about to cut, not in continual search for the point of his instrument. And how can he feel where the point of his instrument lies unless the point be central; and how can the point be central except the scalpel be truly lancet-shaped? How few of our instrument makers turn out truly balanced central pointed scalpels. Fewer still can keep our scalpels in order without grinding the point away until it reaches the level of the back of the knife, giving us, instead of the beautiful, sawing, lancet-shaped curve of edge, an edge belly-shaped, flat toward the point, ready to be blunted by the first plunge into the skin.

*The Director.*—Another simple, universally used instrument, is the "director," which is rarely met with of good form, as generally offered for sale. It is straight, instead of having an elegant double curve, slight indeed, but such as would enable the surgeon to insinuate the instrument along curving passages, or more conveniently to bring the point to tell from beneath against the skin. It is often too deep or too narrow in the groove, and the groove, instead of shelving off to a vanishing-point and allowing the bistoury to continue its course, ends in a full stop, and spoils both the course and the point of the knife. Another faulty point is the handle. A director should be capable of being held firmly, the handle being substantial, not thin, long enough and not stumpy, and horizontally roughened and not slippery. You may perhaps think this a long tale about a small matter.

*Catheters and Sounds.*—The metallic catheter or sound is, or was, an instrument used by nearly every medical man. As with the scalpel so with the catheter, the surgeon should be able to feel, that is to be conscious, where the point of the catheter or sound is, and without seeing it, as he cannot have his eye upon the point when in use. In order that we may feel where the point of the catheter is, the straight stem should be continued into a true curve, that is, a segment of a single circle, probably exactly a quadrant. And yet what do we generally find? A curve, which at one part is the curve of a one-sized circle, at another part is a curve of a circle of a different size, or the catheter may terminate with about one inch of its length which is a segment of no circle whatever. The same applies to sounds, and even to some sets of Lister's sounds. My own had to be remodelled and brought to a correct curve.

*Volsellum Forceps.*—Perhaps no single instrument has been made in greater variety of form and shape than the "volsellum forceps," of which I possess a considerable variety. The principle on which the majority are formed is that of one, two, or more pairs of teeth or claws, or fangs, which sometimes fit accurately when closed, so as to present no projecting points, sometimes expose unguarded points which interfere with easy manipulation, and may prick the surgeon's finger when guiding them to their destination. Probably the best of this class is the hawk's-claw forceps, designed by Mr. R. B. Hewetson, of Leeds, copied from a bird's claw. It consists of five prongs, which fit so accurately at the points as to present when closed, a smooth rounded surface. Forceps of this class are essentially grouped hooks, and like hooks are apt to tear through tissues when any forcible drag is put upon them. The needs of abdominal and uterine surgery have, however, created a demand for a form of forceps which shall be capable of maintaining a firm grip without tearing of tissue, even under the stress of considerable drag. This need forced itself upon my attention when working out a satisfactory method of rapid dilatation of the os and cervix uteri. Marion Sims taught us the value of drawing down the os uteri by a hook. But the hook will not provide for a prolonged and powerful drag, such as is needed to fix the uterus in dilating the os internum. The other forms of hook were tried, and the claw-like volsellum forceps, and all at times disappointed me, until, taking a hint from a small pair of forceps which were found in the collection at the Leeds Infirmary, I had made by Messrs. Weiss a pair of forceps which has proved most satisfactory. The teeth, seven in number (three and four), are short, and so fit into one another when closed, that they not only act as seven hooks, but also close upon and nip firmly the tissues that lie between them. They are also provided with a catch, so that they will hang, or can be held by a single finger passed through one ring. The key to satisfactory uterine dilatation is the power of holding the os uteri down toward the vulva, and no form of forceps that I have met with is equal in efficiency to the one now described. Had I possessed them years ago, they would have saved me hours of work, and perhaps sometimes failure, in operations for vesico-vaginal fistula.

*The Twitch Tourniquet and Torsion Clamp.*—Some years ago Messrs. Weiss made for me an instrument

named the "twitch tourniquet," which has not yet been described in print. It has proved useful to me on many occasions as an easy means of controlling the cord in extirpation of the testis, as a more handy and manageable clamp in amputation of the penis than the ingenious vulcanite plate of Clover, and as an aid in removal of intra-uterine fibroma. The idea was suggested by the "twitch" used by veterinary surgeons for controlling horses by a hold on the upper lip. The idea stood me in such good stead when in a great fix not long ago that I have developed out of it the "uterine torsion clamp," designed to do the work of Kœberlé's and Lawson Tait's clamp in hysterectomy. The emergency was as follows: A few months ago, when operating on a supposed simple ovarian tumor, at the Leeds Infirmary, I unexpectedly found that it was so completely united with the back of the uterus that I must include the uterus in the pedicle. Kœberlé's clamp was produced, but the screws would not bite, and we had no other clamp at hand, We were suddenly face to face with an extreme difficulty. Mr. Littlewood, who was assisting me, suggested the wire *écraseur* as a way out of the difficulty, and the thought struck me at once that, having surrounded the pedicle with the wire, I might tighten by torsion instead of by the mechanism of the *écraseur*. The result was so satisfactory that I determined to modify the "twitch tourniquet" so that it might admit of the use of suitable flexible wire, which, having been tightened by torsion to any desired extent, could be released and left on the pedicle as a clamp.

*Conclusion.*—Those of my hearers, and readers—for an address to the British Medical Association is practically delivered *urbi et orbi*—those, I say, who have expected to hear a triumphant record of the astonishing progress of surgery, or a pæan on our local surgical achievements, may be disappointed at the humble theme which I have attempted to work out, and may think that I have failed to do justice to colleagues who have done much to leave a mark upon the progress of surgery. My aim has been not to sound the praise of individuals, much as they deserve it, but rather to leave an impression on the practice of surgery.

If any of you shall have been induced to study afresh, and from the point of view put forward in this address, the question of division of an artery between two ligatures, the bearing of the sphincter ani upon the surgery of the rectum and disturbed functions of the colon; the substitution of Lister's sounds for older methods in the treatment of stricture; the emancipation of "drainage" from red-tape rules; and, lastly, the proper method of administration of ether so as to raise it as an anæsthetic to a position of incontestable superiority to chloroform—if such should be the outcome of this address, your time in listening will, I trust, not have been wasted, and my labor in composing it may not have been in vain.

## SIMPLE METHODS FOR MAKING CORROSION PREPARATIONS SHOWING THE GROSS ANATOMY OF LARGE VISCERA.[1]

By J. WEST ROOSEVELT, M.D.,

ATTENDING PHYSICIAN AND ASSISTANT PATHOLOGIST TO THE ROOSEVELT HOSPITAL; VISITING PHYSICIAN TO BELLEVUE HOSPITAL, NEW YORK.

My object in presenting these preparations of the heart, lungs, and kidney is to direct attention to the value of the method for study, and also to show that little but patience is required to make them. It is needless to say that no originality is claimed. Some of the details have not, however, been described before, as far as I know.

Corrosion preparations are usually broken by handling; by currents in the corroding fluids; by unequal corrosion; and a consequent tendency of the specimen to turn suddenly over in the solution as its centre of flotation is changed, or to break because of the unequal support given when the ends of the specimen tend to float higher or lower than the middle.

It is evident, therefore, the first thing is to avoid handling. This is easily done if the organ be fastened to a proper support. All the indications are fulfilled if the various tubes be fastened together and to some support, and if the corroding agent be so applied as to avoid making currents. The support should be arranged so that it prevents sudden turning, and also so that it holds the organ at nearly the same position in relation to the corroding agent, if this latter rise or fall, or if the organ changes its centre of flotation. The method first described applies to all viscera with which I have experimented (heart, liver, spleen, pancreas, and kidneys) except the lungs, which require special treatment.

The cannulæ may be of glass or hard rubber, and are inserted and fastened in the usual way. The injection may be made with a syringe or in any other manner. All the pipes should be as large as possible.

After the cannulæ are in place the organ is put into a rather deep glass jar, nearly filled with warm water (102°–110° F.).[1] The injection is then made, and the organ removed to another jar containing cold water. As soon as the mass has cooled in the cannulæ the organ is raised by them so that they are above the water-level. A short, stout **S**-hook of glass is now tied either to the cannulæ or to the injected vessels. After this the vessels and the hook are all fastened together, either by pouring melted paraffin over them, or by means of melted shellac. It is then hooked over a piece of thin rubber tubing, which is to be fastened across the mouth of the jar after most of the water has been siphoned off. This tubing should be sufficiently elastic to allow considerable rise and fall of the viscus with the changing fluid level, and also allow it to sink deeper as the lower parts become dissolved. The water is next siphoned off until only enough remains to support the specimen. Strong hydrochloric acid (commercial) is then poured over the surface of the organ in quantity sufficient to raise it nearly to the top of the jar. The rubber tubing, which has until now been left loose, is next fastened to the jar or some convenient object. (It is frequently better to have an independent support for the elastic tube. A shallower dish may then be used for the specimen, and this may be put over a deeper one. The various corroding agents may then be allowed simply to overflow the sides of the shallower dish and be siphoned off from the deeper when necessary.) Sufficient strain should be made on the rubber to lift the specimen partly out of the fluid, so that a small portion of its surface is exposed.

After the specimen has been twenty-four hours or more in the acid, this may be replaced by water, poured in through a funnel, the tube of which is carried down to the bottom of the jar. If water supply be available, a glass tube attached to a faucet by rubber tubing may be carried down to the bottom of the jar and a gentle stream turned on. The specimen may remain from one to twenty-four or more hours in water. After this more hydrochloric acid may be added, and the process repeated as often as necessary.

When the specimen is clean it is carefully removed from the jar. If it be very large, several cords may have to be attached to it at different points. It is better, with delicate specimens, to remove the fluid by a siphon than to try to lift them. The siphon makes less current. If paraffin be the basis of the injection, varnish may be now applied, in the manner soon to be described, before any further manipulation.

In dealing with the lungs the process is different, since these organs tend to float so high. If possible, they should be injected in the unopened thorax, the latter being subsequently opened and the lungs treated *in situ*. As this procedure is rarely possible in the human subject, we must, if a fairly accurate specimen is desired, take a cast of the

[1] Read before the New York Pathological Society, April 24, 1889.

[1] If cold masses be used, of course no warm water is needed.

pleural cavity in plaster, and from this make another in wax or paraffin. The lung may be laid in the latter and carried through all subsequent processes. For most cases it is sufficient to proceed as follows: One of the short arms of a glass T-tube is introduced and tied in the bronchus, and cannulæ are tied into such vessels as it is desired to inject. To the long (perpendicular) arm of the T a rubber bulb, such as is used in atomizers, is attached. The injection mass is introduced through the other arm. A piece of rubber tubing, having a clip on it, is put on this latter arm. The clip being closed the lung is inflated by means of the bulb with air. It is then placed in a shallow dish, partly filled with melted paraffin. Some of the latter is poured over all the tubes. The injecting syringe is now inserted into the rubber tube attached to the T. The clip is removed and the injection made. When enough of the mass has entered, a little cold water is poured over the T, and the mass is thus hardened and the tube plugged. The artery is next injected, the vein last. After the injection has cooled a little, several shallow incisions are made on the upper surface. These form a holding-ground for the acid. The upper parts should be first dissolved. Chromic acid in powder is the best agent I have found for this. It is spread over the surface and wetted a little and allowed to deliquesce. It penetrates with wonderful speed. It should be washed off with hydrochloric acid. If the chromic acid does not change to a dark brown color in a few minutes, and rapidly eat its way into the tissue, a little fluid containing organic matter, as saliva, will start it. One danger in the use of this acid is that it sometimes produces a good deal of heat, especially if it come in contact with fat. The hydrochloric acid or water will prevent this. The green color produced by the chromic acid reduced by hydrochloric is easily washed off in water acidulated with nitric acid. A dirty white precipitate may be produced on the specimen. This also is washed off without difficulty. The lungs should not be warmed lest the injection flow too readily.

Most of the masses which I have used have been made of paraffin, one to three parts; yellow wax, one part; and melted dammar, about one-twentieth part. Paraffin of rather high melting-point seems best. This is melted with the wax. The gum is melted in a separate dish. Both the paraffin-wax mixture, and the gum must be raised to a high temperature and then mixed, the gum being added in small quantities at a time and well stirred.[1] It is doubtful whether this mass will stand our summer heat. Probably others made of varnish will be better. The paraffin mass is much strengthened if, after the specimen is dry, a quantity of "fixative" varnish be sprayed over it, so as to coat it completely.

The coloring agents which seem best are vermilion, cobalt blue, chrome green, and chrome yellow.

Cold masses I have only recently begun to use. They have many advantages over the hot. My experience with them is not sufficient to enable me to speak of them. Many beautiful preparations have been made with them by others.

In conclusion, let me say that to make corrosion preparations these points must be remembered: 1. Fasten the tubes together to some support. 2. Do not change the fluids too rapidly. 3. Do not handle more than is absolutely necessary, and when you must, always remember what you wish to avoid injuring. 4. The process cannot be hurried. The only thing to do is to fasten everything securely and wait till the specimen is finished. This merely needs patience.

---

Cremation in Berlin.—The police authorities of Berlin have recently refused the request of the Cremation Society to be allowed to cremate the bodies of all those who had signified their wish to be so disposed of.

[1] This mass melts at a rather high temperature, but it remains liquid at a temperature sufficiently low to be safe.

## ON THE MODERN VIEWS OF THE ETIOLOGY OF RHEUMATISM, WITH A CLINICAL CONSIDERATION OF THE TREATMENT OF THE SAME.

By LEONARD WEBER, M.D.,

NEW YORK.

In preparing myself for the opening remarks of a discussion on the above subject, before a recent meeting of the German Medical Society of this city, I found not only a good deal of interesting material in recent publications, but also some valuable clinical observations recorded in my note-books, and thought it might be well to elaborate these matters in the subsequent paper.

Inflammatory rheumatism—polyarthritis rheumatica—is known to us as a disease well characterized by fever, by inflammatory affections of the joints and the heart, and by various complications, and is now supposed to have a distinct etiology and pathogenesis. To the labors of Immermann, Edlefsen, Friedlander, and their pupils, we are mainly indebted with regard to a decided modification of our views of the origin of the disease, and the following data may now be considered as nearly proven:

1. Inflammatory rheumatism is not produced by taking cold, *i.e.*, refrigeration of the heated surface of the body.

2. It belongs to the class of miasmatic infectious diseases, assuming an epidemic-like character at certain times, in so far as we are apt to see a larger number of cases when there is decreasing rain and moisture, while with an increase of the same the number of cases is diminished.

3. Rheumatism is also a house disease, the underground of houses in certain locations being infiltrated with the virus, which will be set free after prolonged dryness. and by the air-currents carried into the apartments. One or the other of the three main symptoms of rheumatism may be absent, and yet the affection in question has the same etiology, as, for instance, acute muscular rheumatism, acute endocarditis, acute sero-fibrinous pericarditis, and a good many cases of chorea, though they may not just follow an attack of rheumatic polyarthritis. Furthermore, Immermann has shown us a masked form of rheumatism, presenting itself in the shape of neuralgia of the trigeminal, sciatic, spinal accessory, or other nerves. In March last I had a gentleman under my care who, having repeatedly suffered from gout and rheumatism, had at that time an exquisitely painful affection concerning the left spinal accessory and branches of the fifth pair, associated with slight febrile motions. I failed to relieve him until I gave him the alkaline and salicylate remedies in large doses, when he rapidly improved and got well.

Edlefsen goes further than Immermann, and says that all neuralgias, with the exception of those caused by diseases of the central nervous system, syphilis, meningitis, or intermittens—have an etiology in common with articular rheumatism. Urticaria is considered of specific rheumatic origin by Friedlander and some other authors, but I do not remember more than a very few cases of this affection which showed themselves amenable to antirheumatic remedies in my hands; while the majority appeared to me of neurotic origin, requiring constitutional treatment, and proving more or less refractory at that, particularly as far as the subacute form is concerned.

With regard to scarlatinal rheumatism the opinions are as yet divided—Immermann and others believing the scarlatinal poison to be also the cause of the joint affections, Edlefsen and his followers considering scarlatinal rheumatism to be articular rheumatism, so that a mixed infection would be present in such a case.

Among the many cases of scarlatina that have come under my observation there have been so few of them associated with articular rheumatism that, by this somewhat negative experience alone, I am inclined to believe in the identity of scarlatinal and articular rheumatism. And further than that, rheumatic diseases had occurred in some of the houses where I saw such complications, and

the usual antirheumatic treatment was of good service in relieving them.

It would appear from the above views that the field of rheumatism has been rather enlarged; but we shall not find it so, if we come to separate from it a number of diseases which do not belong to it any longer. First of all, the many painful affections of the locomotor apparatus, some neuralgias and paralyses of motory nerves—particularly of the facial—which may be, and often are, produced by a rapid cooling off of the surface of the part in question, and eminently so when that surface has been hot and perspiring. Erb and Immermann propose to use the word *refrigerate* in designating all such cases, which have thus far been erroneously called rheumatism. Refrigeration is the most important, if not the sole factor in their etiology, and when we speak of refrigeratory myositis, or myalgia, or facial paralysis, we know exactly what we mean by it.

And we have further to expunge from the chart of rheumatism the painful affections of the muscles after severe exertions (Robin's pseudo-rheumatism), the rheumatoid complications of gonorrhœa, chronic bronchitis—bronchectasie, hæmophilie—all of which are due to poisonous influences different from that of rheumatism. Also rheumatoid purpura, or s. c. peliosis rheumatica, as shown already by Senator ("Ziemssen's Spec. Path. and Ther.," vol. xiii., 1, p. 62). I have seen a case of severe and widely spread purpura in a man, fifty years of age, associated with inflammatory hypertrophy of the liver, that ended in cirrhosis, of which he died; another with chloranæmia, in a hard-working girl, twenty-two years of age; another with mercurialism, in a syphilitic man, thirty-six years of age; a number of them of very moderate extent and severity in neurasthenic and anæmic persons, but I have not had a case in which antirheumatic treatment has been of any service. The pains in the limbs and around the joints in such cases are due to œdema, and the more or less cachectic general condition, but not to rheumatic inflammation.

Bacteriological research has not succeeded in advancing our knowledge as to the etiology of rheumatism, but more has been learned by observations of another kind, for the origination of which we are indebted to Edlefsen. In a paper read before the Fourth German Congress for Internal Medicine, in 1885, he argued pretty conclusively that the theory of the influence of cold (refrigeration) was untenable with regard to rheumatism, and showed that while there was a decided connection between the mean temperature of the months and the frequency of laryngitis and bronchitis, the existence of the same connection could not be maintained as to articular rheumatism; and he further proved that the number of cases of rheumatism become less as rain and moisture increases, and more with the decrease of the same, and that pretty frequently a series of cases would occur in one and the same dwelling, and the adjoining houses in particular streets. These observations would show that inflammatory rheumatism is a miasmatic infectious disease, that its virus is of an organic nature and often has its lodgement in the underground of dwellings. These statements were supported at the time of the discussion of his paper by Jürgensen, and Friedlander; later on, by Hirsch, Mantle, Feltkamp, and others. My own records show that the greater number of my cases of polyarthritis rheumatica occurred in February and March, and again in the hot and dry summer months. It might be said that butchers, grocers, marketmen, and saloon-keepers, for instance, which form the majority of the cases I treated, are just the persons who are more exposed to cold than others, and that alone might account for their rheumatism on the basis of the old theory; but they are also the persons who carry on their business, and frequently live in dwellings which are habitually damp, and the underground of which furnishes, in a most luxurious way, the conditions required for the development of the rheumatic poison. In a similar way the frequency of rheumatism among sailors could be explained.

To be sure, frequent exposure to cold and its consequences might create a predisposition to rheumatism, just as we know of well-observed cases where acute rheumatism broke out after a sprain or distortion of a single joint.

If we accept the modern views of the etiology of rheumatism, and put it into the group of the miasmatic infectious diseases, to which it apparently belongs, it will not be difficult to work out a general idea of the pathogenesis of the disease. There is a virus present in the circulation which in one case attacks principally the joints, the endo-, and the pericardium; in another, the muscles; and in another, the nerves, etc.

*Therapeutics.*—Among the many valuable remedies with which modern chemistry has presented us salicylic acid stands in the foremost rank, and its therapeutic powers in inflammatory rheumatism may be considered as great as those of chinin in intermittent. Many of us prescribed the alkaline treatment in the early period of our practice, basing it upon the lactic-acid theory then in vogue, and combining the same with the free use of chinin to control the rheumatic fever. And the results obtained, were they generally unsatisfactory? By no means. The great majority of the patients got well; but more of them so treated drifted into the subacute stage, or acquired endocarditis, leading to valvular disease, or died of hyperpyrexia, than of those that are given the salicylates in the proper way. Experience has taught me that salicylate of soda, mixed with its bulk of bicarbonate of soda, is borne better by the stomach than the salicylate by itself, while it loses none of its efficacy. For a number of years, therefore, I have prescribed, in acute rheumatism, fifteen grains of each salt to adults, and one-half of that to children, every three hours during the day, and the night also in severe cases, until the temperature and pulse became normal, and that very generally was the case on the third or fourth day from the beginning of the treatment. Dr. A. Seibert, of this city, a careful observer, to whom we are also indebted for collecting some valuable statistics which appear to confirm the theory of the miasmatic-infectious origin of rheumatism, prefers giving the salicylate every hour, in order to overcome the action of the rheumatic virus as soon as possible. When he finds the stomach intolerant to the remedy he introduces it by the rectum, and gives it, in children's practice, always that way. He reports to have seen many cases in which pulse and temperature became normal, and the joints free from pain and swelling, in a day, and considers this method perfectly safe and satisfactory. Now, although the salicylate is a great remedy, it is neither omnipotent nor can it be administered in every case with safety and comfort. I have had to deal with many a case in which the head and stomach would not bear it, or a weak heart would soon forbid its use, and others in which it did no good.

There are some observers who have used antipyrin, or antifebrin, or oleum gaultherii in such refractory cases with confidence and success; have even gone further and laid aside the salicylate, and operated with the remedies just mentioned in preference to the standard one. I regret to say that my experience with them in rheumatism has not been such as to induce me to praise them highly. Whether my failure was due to want of patience or want of courage to give them in large enough doses, rather than to the inefficacy of the remedies, I do not care to inquire into now, but am ready to throw those three, and the phenacetin besides, overboard for salol, a compound which has yielded me very good results in cases where the salicylate failed to act or could not be continued. To illustrate by an example. Mrs. S——, aged thirty-six, quite stout and rather strong, pulse regular but weak, heart apparently sound, had inflammatory rheumatism some six years ago, being laid up with it for eight weeks at that time. In March last she was taken with pneumonia of regular type, of which she recovered completely in the course of the second week, and two or three days

thereafter quite an acute attack of inflammatory rheumatism set in, with high fever and all the other usual symptoms, except endocarditis, of which there was no sign at any time of the four weeks during which she was confined to her bed. The salicylate given during the first week failed to cure, and likewise antipyrin and phenacetin given in the second week. The alkaline remedies, ordered in large doses, in conjunction with the tincture of colchicum all during the third week, brought some relief, but did not prevent relapse and extension of the disease to some joints of the upper extremities at the beginning of the fourth week. I then gave of salol fifteen grains every three hours, *i.e.*, five times a day, and had the swollen joints blistered *coup sur coup*, and the patient carefully nourished and stimulated. At the end of that week she was relieved of all troublesome symptoms. I continued the use of salol, *refracta dosi*, for another week, when she was discharged cured.

It would be easy to add five or six cases more of a similar nature, but this would be needless supererogation. I prefer to say a few words more of the comparative frequency of relapses of acute rheumatism, the subacute forms, and those cases in which the disease settles, so to speak, in one or more joints, invalidating or crippling the patient. To expect here to cure by a prolonged course of the salicylate or salol, or another of the modern specifics, would be a vain hope indeed, and end very probably in disappointment to both physician and patient. A great deal can be accomplished, however, and many a case cured by a bold but judicious and prolonged use of the alkaline treatment, with the iodide of potassium in every case where the stomach will take the latter, no matter whether there is a combination with syphilis or no. I have found such treatment very good in rheumatism concerning fat persons, and those bloated with malt liquors when they have not yet anæmia and weak heart. Where the latter complication is associated with rheumatism it is good practice to improve the patient's condition by appropriate general regimen and the exhibition of the muriate tincture or other preparations of iron in large, and digitalis in small doses, and then proceed with specific treatment, prolonged warm baths—natural or artificial—change of air and domicile when there is cause for it, sea-voyages, and the like.

To cite one or two cases may be sufficient for illustration. Mrs. W——, aged thirty-four, had had rheumatism for about two years before I saw her in 1884. There was no valvular disorder, but one wrist, shoulder, and knee-joint were the seat of old exudation, more or less swollen, and distorted and painful, and the patient was scarcely able to be about, and quite unable to do her work. Beginning with a short course of the salicylate, which I am in the habit of doing in almost every case, and generally with some benefit as to recent exudation in old cases, I followed it up with a solution of iodide of potassium and liquor potassæ, which the patient took steadily for nearly six months, when she was free from rheumatism, looked well, and had the use of her limbs as good as before. Her means were such that reasonable care and good food could be provided; but nothing in the way of baths, change of air, or other adjuvants to assist the action of the remedies. Syphilis was not present. Further, I was consulted by a gentleman, some years ago, who suffered in a similar but more pronounced way, and in whose case syphilis could also be excluded. He said he had had all the necessary remedies, and enough of them, would take no more drugs, but was ready to follow any other good advice that I might be able to give him. I asked him if he was a good sailor, and upon receiving an affirmative answer I suggested a prolonged sea-voyage in a sailing vessel. He did not relish the idea of being on board of such craft, but immediately engaged passage on a slow but comfortable steamship line, and crossed and recrossed the Atlantic six times in the course of the summer, when he considered himself cured. On his third voyage he was already able to walk the deck without support, and had good use of his limbs during all the others. However, even after an apparently perfect restoration from chronic rheumatism, the proneness to relapse remains, and the patient, if not already taught by experience, ought to be informed of it, as he will then be more readily inclined to undergo a further course of treatment, which need not be long when begun without delay. Immobilizing dressings I have often used in the subacute form of rheumatic joint affections, when I found much tenderness, swelling, and gelatinous exudation that would not yield to medical treatment. Such appliances were always productive of great comfort to the patient, never did any harm, and very often favored absorption and helped to cure. Blisters over the joints in the acute, relapsing, and subacute forms—an old mode of local treatment, by the way—I have been taught by experience in numerous cases to value highly, and never hesitate to apply them wherever the exudation does not quickly yield to medicine. The ice-bag I have never ordered to be laid over a joint inflamed acutely by rheumatism. I have never seen any good accomplished by it, but remember a few cases in which the rheumatic disease appeared to linger in the very joints which had the ice-bag on.

That a great many joints, more or less diseased and quite unfit for use by chronic rheumatism, have been improved and cured by massage and medical gymnastics applied by experts, there is not the least doubt. But there still remain a number of chronic cases, in which such an amount of mischief has heen done that various joints may be in a more or less disorganized condition, crippling the unfortunate patient for life.

In the experience of Dr. F. Lange, of this city, a number of cases of this kind have come under his care, in which searching inquiry failed to elicit any other cause but rheumatism for the destructive joint-lesions, and in which more or less surgical treatment was required to afford relief.

25 West Forty-sixth Street.

The Action of Astringents.—In an experimental inquiry upon the mode of action of astringents, Dr. R. Heinz, of Breslau (*Virchow's Archiv*, 116, Hft. 2), finds that, as regards their property of contracting vessels, the minimum strength of solution is, of corrosive sublimate, 0.005 per cent.; of nitrate of silver, acetate of lead, and sulphate of zinc, 0.01 per cent; of cupric sulphate, perchloride of iron, tannin, and alum, 0.05 per cent.; while, in respect to the degree of vascular contraction excited, they may be ranged in the following order: Nitrate of silver; acetate of lead and sulphate of zinc; corrosive sublimate, cupric sulphate, perchloride of iron; tannin and alum. Upon the interesting question of the prevention of inflammation by the use of these substances, Heinz made many experiments on the mesentery of the frog. He found, in the first place, that when the exposed membrane was treated with such solutions, the leucocytes, although accumulating within the vessel along its walls, did not exude and collect outside the vessel, as in the ordinary experiment of mere exposure of the membrane, which is kept moist by salt solution. If a certain amount of inflammation were excited prior to the application of the astringent, the latter caused an immediate arrest of the process. That this was not due to the narrowing of the vessels was proved by using solutions of greater strength (*e.g.*, of tannin, one-half per cent.; alum, two and a half per cent.), whereby dilatation of the vessels is caused. Still higher concentration of the solutions injure the tissues and excite inflammation; and yet, curiously enough, if the application of such be continued for a longer time, inflammatory action is held in check.—*Lancet.*

Paramonobromoacetanilide is the name of a new substance experimented with by Cattani, of Milan, and which he calls, on account of its most noticeable property, antisepsine.

# THE MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

New York, August 31, 1889.

## THE ARMY MEDICAL SERVICE.

THE Medical Department of the Army has recently made a change in its method of filling vacancies in its ranks. Formerly a medical board of some permanence held its daily sessions in the Army Building in this city, and to it all candidates recommended by the Surgeon-General and the Secretary of War were referred for examination; but as the work involved in filling vacancies did not suffice to keep the board fully occupied, it was dissolved in the interests of economy, for the utilization elsewhere of the services of its members. Under the new system a special board is convened to meet the requirements of the service. As soon as it is ready for work fifteen to twenty-five candidates appear before it at a stated time. Not all these undergo the full course of the examination. Some drop out on the first day on account of physical disqualifications, and others from day to day thereafter as they become discouraged by finding, on careful study, how poorly their text books sustain them in certain matters which they had that day discussed in writing for the scrutiny of the examiners. On the conclusion of their examination a second detachment of fifteen to twenty-five is ordered up and disposed of in like manner; and so on until the whole of the candidates have undergone the ordeal or dropped by the wayside. The aggregation of its work enables the special board to examine in a month as many men as were examined by the old board in a year; but this economy of the time and services of the medical officers constituting the board is not all clear gain to the service. Under the old system a young graduate who desired to appear for examination was able to accomplish his purpose shortly after he took the initiatory steps, because the board was always there; but now, he may have to wait a year before a board is convened to examine him. Meanwhile some opening in civil life may be presented, and the promise of its future changes his views as to the manner of his professional career; or, the temporary pressure of some engagement, family affairs, or personal ailment may prevent him from appearing when the board is ready—and the young years of life are too valuable to be spent in waiting. Formerly the army secured every capable man who felt a vocation for the military life, but now some of the best men will slip away from it—between the sessions of the board.

Hitherto the character of the examinations for position in the Army Medical Department has been as a sealed book to those who were most interested. We print elsewhere in this issue a set of the questions submitted to candidates by the board recently in session. At the end of the written examination the trials culminate, and end in some clinical work in the hospital and operations on the cadaver. After this the successful men find themselves almost immediately commissioned and under orders from the War Department, for as the examination was held to fill existing vacancies no time is lost in filling them, now that the men have been found.

For a young man who has no financial resources or family influence to protect him during the building up of a civil practice the army service offers special inducements. The passed candidate enters at once into a position of responsibility, with the rank, pay, and emoluments of a first lieutenant of cavalry, a rank which is seldom attained by the graduates of West Point under a service of ten or twelve—usually twelve—years as a junior or second lieutenant. At first he may be sent to some large post in the East, where, under the orders of an officer of long service, he will gather experience in the military as well as medical line of his duties. Then he goes out West and has a post of his own, when all the responsibilities of his profession will press heavily on him, and, on account of his inability to call in others for consultation, make him cultivate that preparation for the management of emergencies and difficult cases which gives self reliance to a medical man. During this time his expenses are a trifle compared with his income, which may be largely increased by private practice in the neighborhood of his post, so that at the end of a few years he has saved enough to enable him to settle in any locality if he find army life to be not all that his fancy painted it. Usually, however, the inducements for him to stay, held out at the end of five years' service, largely outweigh all other considerations. Some of these are: the rank of captain, which is reached by the line officer only after a quarter of a century of service; a ten-per-cent. increase on his pay as a captain; a leave of absence for four months, with a trip to Europe, if desired; and, as a matter of fact, not many of those who have stayed for this length of time think now of resigning. The grade of major is not usually reached until after twenty years of service, but as an offset to this, every period of five years brings an additional ten per cent. of pay, until forty per cent. accrues about the time that a majority is attained. At one time this rank of major was the highest that a medical officer could look for; but now that the corps has six colonelcies and ten lieutenant-colonelcies, besides the Surgeon-Generalcy, and a compulsory retirement law which enables the younger men to move up as the older men reach the age of sixty-four, every medical officer can look to retirement with seventy five per cent. of a colonel's income as a provision for his later years.

The medical officer of the army has one grand advantage over his professional brethren in civil life. He is free from all the financial worries and anxieties which break down so many men who have to struggle for their income. There is no uncertainty about his future. He has no occasion to provide for the proverbial rainy day. If sickness assail him his income drops into his hand monthly, as if he were in the steady performance of his work; and in old age he is on the retired list. The won-

der is not that so many of our young graduates go before the Army Medical Board, but that all of our best men are not seduced into the ranks of the army.

### STATE EXAMINATIONS FOR LICENSE TO PRACTISE.

ONE by one the different States are swinging into line along this very important reform in medical education, and it seems a pity that the conflict of various interests delays progress in our own State. We have read with interest the report of the Minnesota Board of Examiners, as given through the columns of one of our Western exchanges. The work of the board has extended over two years. Of ninety-four candidates, thirty have been rejected.

In looking over the list of questions of an examination just held, we are impressed by their straightforward character. They ask for just what every practitioner should know. The number of them is greater than is generally given on our leading college papers, but they bear, on the whole, a more practical nature. Special papers on histology and pathology are inserted in addition to the more general questions in medicine and surgery, requiring knowledge on these points.

These satisfactory results have not been attained without opposition. Low grade institutions in neighboring States, whose graduates could not pass the Minnesota examinations, have endeavored to secure repeal legislation, but fortunately the law has stood. It is not without some chagrin that we, in this State, contemplate the advances which are being made in these respects in other communities. It is not a matter affecting sects or particular institutions, but rather the standing of the profession in its broadest sense, and the welfare of the community. The fact is that the greatest advance in this direction has been made by States, with the exception of Virginia, which are not generally regarded as medical centres. In our own State there are many conflicting interests to harmonize; not so many, however, but that each one could have a full representation in a State Board. Mutual supervision would be sure to prevent any one side from securing an undue advantage.

Some details of the Minnesota statute are not without interest. The percentage required for securing a license differs with different subjects. Sixty-five per cent. is required from all applicants in materia medica, surgery, practice of medicine, obstetrics, and gynecology. Fifty per cent. is required in all other branches from graduates of less than five years standing; for all others, but thirty-five per cent. is required in these same remaining branches.

### A NEW OPERATION FOR LACERATED PERINEUM.

A NEW operation has been proposed by Mr. Alexander Duke, for the repair of lacerated perineum, which seems to possess some advantages, in certain cases at least, over those at present in vogue. The procedure, which is described in the Dublin *Medical Press* of May 9, 1889, is apparently quite simple, and if it prove to be as efficacious as Mr. Duke believes it will, it ought to take rank among the recognized operations for the relief of this condition.

The method is in brief as follows: The patient is placed either in the lithotomy or Sims position, the left index-finger being introduced almost its entire length into the rectum; a long, straight, double-edged bistoury is made to pierce the tissues in front of the anus at right angles to the vulva; and, guided by the finger in the rectum, is made to penetrate the septum for two and a half inches upward, the incision being enlarged laterally to two inches at least, as the knife is withdrawn. On the two points of incision being pressed together from side to side a lozenge-shaped opening appears, and when all the sutures required have been introduced and are properly adjusted and approximated, the two cut surfaces are brought into direct apposition. The sutures are introduced by a strong cycle-shaped needle with eye in the point mounted on a handle, strong silver wire being the suture preferred. The needle is introduced at the centre of the skin incision below, and, guided by the finger in the rectum, is made to travel over the cut surface to its full extent above, describing the arc of a circle, and, on the point of needle appearing directly opposite, it is threaded with the suture and drawn through. When all the necessary sutures have been introduced and approximated, a finger of each hand passed into the rectum and vagina will at once recognize the gain in thickness of the septum, the external tissue being pushed fully an inch forward from the anus, and forming a thick and solid perineal body. The incision being a deep one, on union taking place between the raw surfaces, a considerable depth of support must be afforded where a pessary is required, or where there is much tendency to prolapse of the uterus or vaginal walls.

Mr. Duke's experience of the operation, although up to the present limited, has satisfied him, he says, with the results, and, there being no loss of tissue whatever, should the operation fail, it cannot add any difficulty to a subsequent one. The following are the advantages which he claims for the operation:

1. The simplest of performance as yet proposed. No danger of hemorrhage, the surfaces being brought together at once, and the wound is dry and clean.

2. No danger of sepsis, as the incision is not open for the admission of any discharge from either vagina or rectum during the healing process.

3. No loss of tissue, and consequently no harm done should the operation fail.

### PHOSPHORUS IN THE TREATMENT OF RICKETS.

THE use of phosphorus in rickets, so much vaunted by Kassowitz and others a couple of years ago, has not, we believe, found much favor in this country. A very extensive trial of the remedy has recently been concluded by Dr. L. B. Mandelstam, of Kazan, who publishes the results in *Vratch*, Nos. 5, 7, 9, 10, and 11, 1889. These experiments extended over a period of nearly three years, and the number of patients upon whom the phosphorus was tried was 450, their ages running from three months to four years. Of this number, however, 234 were excluded from the statistics, either because they did not take the phosphorus long enough, or in the proper way, or because the disease in them was not sufficiently pronounced to make the experiment a satisfactory one.

Of the remaining 216 children, 120 were cured, 43 were markedly benefited, in 30 no improvement was

noted, and in the remaining 23 the treatment was discontinued on account of some intercurrent disease. The remedy was given dissolved in cod-liver oil, in the proportion of one part to ten thousand of oil, of which a teaspoonful was given once or twice a day. When it was not deemed advisable to give cod-liver oil, the remedy was administered, after the formula of Kassowitz, in a mixture composed of $\frac{1}{100}$ part of phosphorus, 15 parts each of gum arabic and sugar, 30 parts of almond oil, and 40 parts of distilled water. Dose, a teaspoonful once or twice a day. No other remedy was employed, except when diarrhœa was present, and then an attempt was made to cure this before giving the phosphorus.

The following are the conclusions which the author feels himself justified in formulating as a result of these experiments:

1. Clinical observation justifies fully the employment of phosphorus in rickets.

2. Phosphorus acts better, more quickly, and with greater certainty than any other remedies.

3. This drug, when given in small doses, even for long periods of time, is well borne by children, and causes in them no unpleasant effects.

4. Phosphorus is especially efficacious in controlling the nervous manifestations of rickets.

5. Periodical measurements and weighing of the children, as well as observation of the osseous structures, show that the disease is actually arrested in its course and cured, in the great majority of cases, under the influence of phosphorus.

Another trial of the same remedy was made by Dr. Shabanova, whose report is presented in *Vratch*, Nos. 16, 17, 18, and 19, 1889. She treated 105 patients, and obtained perfectly satisfactory results in 77. In 22 an improvement was noted, and in 6 cases there was an aggravation of the disease while the treatment was being continued. The first effects of the remedy were seen in an improvement in the nervous symptoms, and later, in favorable cases, a change for the better was seen in the general health, and in the condition of the bones and muscles.

## News of the Week.

The Fourth Annual Meeting of the Association of American Physicians will be held in Washington, on September 18, 19, and 20, 1889. The Association will meet in the building of the Medical Museum and Library. The following programme is announced: The President's inaugural address, by Dr. Francis Minot, of Boston; "The Early Stage of General Paralysis," by Dr. C. F. Folsom, of Boston; "Tetany," by Dr. James Stewart, of Montreal; "Tetany and a New Theory of its Pathology," by Dr. John T. Carpenter, of Pottsville, Pa.; "Thrombosis of the Cerebral Sinuses and Veins," by Dr. A. B. Ball, of New York; "Chylous Effusions into Serous Cavities," by Dr. S. C. Busey, of Washington; "Substitutes for Opium in Chronic Diseases," by Dr. J. F. A. Adams, of Pittsfield, Mass.; "A Remarkable Case of Slow Pulse," by Dr. D. W. Prentiss, of Washington; a discussion on "The Relation between Chlorosis, Simple Anæmia, and Pernicious Anæmia, including Leucocythæmia and Hodgkin's Disease," by Dr. Frederick P. Henry, of Philadelphia, Referee, and Dr. F. Forchheimer, of Cincinnati, Co-Referee; "Primary Cancer of the Duodenum," by Dr. E. N. Whittier, of Boston; "Primary Cancer of the Gall-bladder and Ducts," by Dr. John H. Musser, of Philadelphia; "Gastric Neurasthenia," by Dr. G. M. Garland, of Boston; "Specimens from Two Cases of Cretinism," by Dr. W. F. Whitney, of Boston; "The Anatomical and Physiological Relations of Lesions of the Heart and Kidneys," by Dr. H. F. Formad, of Philadelphia; "The Contagium of Diphtheria," by Dr. P. Gervais Robinson, of St. Louis; "A Supplementary Inquiry into the Frequency with which Lead is found in the Urine," by Dr. James J. Putnam, of Boston; a discussion on "The Relations of Rheumatism to Rheumatoid Arthritis," by Dr. William Osler, of Baltimore, Referee, and Dr. Morris Longstreth, of Philadelphia, Co-Referee; "How far may a Cow be Tuberculous before the Milk becomes Dangerous as a Food-supply?" by Dr. Harold C. Ernst, of Jamaica Plain, Mass.; "The Bacillus Tuberculosis," by Dr. J. T. Whittaker, of Cincinnati; and "Hot-air Inhalations in Tuberculosis," by Dr. E. L. Trudeau, of Saranac Lake, N. Y. The annual dinner will take place on Thursday, September 19th.

A Prize for an Essay on Bacteria.—The Dutch Scientific Society in Haarlem offers a prize of one hundred and fifty gulden for a critical review and exhaustive description of the different kinds of bacteria contained in drinking-water before and after its filtration through sand, and of the methods of determining the characteristics of every kind. The judges will award an extra prize of one hundred and fifty gulden if they consider the successful competitor worthy of it. All competitive essays must be filed with the Society's secretary before January 1, 1890, and must be written in the French, Dutch, or German language.

Dr. E. Parsons, of Savannah, Ga., who is said to have been the oldest practising dentist in the United States, died at his home in that city on August 20th. Dr. Parsons was born in Northampton, Mass., in 1806. He was educated in Cincinnati and Philadelphia. In 1843 he went to Savannah, and until a few months ago has been practising his profession.

The Next Meeting of the American Medical Association.—Our esteemed contemporary the Nashville *Journal of Medicine and Surgery* remonstrates with us gently for not having approved fully of the choice of the American Medical Association of Nashville for the place of its next annual meeting. He reminds us that that city is no village, and assures us that it will be well able to entertain as many members of the Association as may put in an appearance. We never once doubted the hospitality of Nashville; it was only the question of its ability to provide for such a number that caused us some apprehension. But we assure our contemporary that our fears are now removed, such is the effect of his convincing eloquence.

St. John's Guild.—Over twenty-three thousand sick children and their mothers have been carried on the fresh-air excursions of the St. John's Guild floating-hospital barge this season, and the sea-side hospital of the Guild at New Dorp, S. I., has been constantly filled to its utmost capacity.

Dr. J. R. Taylor has been elected to the chair of Pathology, Practice of Medicine, and Clinical Medicine in the Medical College of the State of South Carolina at Charleston, S. C., *vice* Dr. John Guitéras, who has resigned, to accept the chair of Pathology at the University of Pennsylvania.

Two More Young Living Fœtuses.—Dr. Henry K. Palmer, of Trinidad, Col., writes that he had had a case similar to those previously reported in these columns. A woman ceased to menstruate on May 31st, and on October 28th was delivered of a living child, nine inches in length, and weighing eighteen ounces. The child was wrapped in cotton and lived for twenty-seven hours after birth. Dr. W. K. Prichard, of Cloverdale, Ind., reports another case of like nature. The mother menstruated last on February 11th, and the child was born on June 26, 1889, four and a half months later. The child lived five days, and its bowels and kidneys acted normally, though the nurse said that the urine looked like milk. The child's eyes were closed at birth and remained so throughout its brief existence. Cases of this sort are not so very rare. It is uncommon, indeed, to see a viable fœtus under the seventh month; but one of five or six months or even younger, if living when expelled from the uterus, must take time to die just as well as an older child.

Dr. Sigmund Lustgarten, formerly of Vienna, has removed to America and intends to reside in New York. Dr. Lustgarten was for some time Privatdocent in Vienna, and in that way is known to many Americans. He is also more widely known as the discoverer of the bacillus of syphilis which is called by his name.

An Epidemic of Diphtheria.—The town of Moscow, O., is reported to be suffering severely from an epidemic of diphtheria. The time will come when an epidemic of disease in a place will be looked upon as a disgrace to the community, as great, if not greater, than would be a series of robberies, or rapes, or of any other crime.

A Case of Inoculated Leprosy.—At the Dermatological Congress held recently at Prague, Dr. Arning gave an account of a case of inoculated leprosy in the Sandwich Islands. In 1884 he was permitted to inoculate a condemned criminal, with the latter's consent. The man whom he inoculated had no inherited taint. The immediate result of the inoculation was negative, but four weeks later the man was attacked with an affection resembling subacute rheumatism without fever. The first joint involved was the left elbow, and then other joints became attacked, the attack lasting for four months. Then occurred some swelling of the left ulnar and median nerves, which subsided in the course of six months. Meanwhile there had developed on the scar at the site of the inoculation a typical leprosy nodule, from which abundant bacilli were obtained. Since Dr. Arning had returned to Europe he had learned that the disease had made considerable progress, and the unfortunate man was now in a condition of marked marasmus.

An Unrecognized Medical School.—The Hudson County, N. J., Board of Health refused recently to allow two young men, graduates of the New Jersey College of Medicine, to register as practising physicians. The college is a new concern, started by some eclectics, and these men were its first graduates. The counsel of the Board, it is reported, said that the college was chartered by the State, and that the Board therefore had no right to refuse to register the applicants. The Board did so refuse, however, for it decided that the college had no right to grant diplomas.

Dr. James L. Cabell, professor of physiology and surgery in the medical department of the University of Virginia, died in Albemarle county on August 13th. He received his medical degree in 1833, and afterward studied in Paris. Dr. Cabell was widely known in Virginia, and had served at different times as president of the State Medical Society, of the American Public Health Association, and of the National Board of Health.

Dr. Herman B. Inches, one of Boston's oldest physicians, died in that city on August 19th, aged seventy-seven. He was a graduate of the Harvard Medical School in 1834.

The Fifteenth Annual Meeting of the Mississippi Valley Medical Association will be held at Evansville, Ind., September 10th, 11th, and 12th. Those who will attend are advised to take receipt for full fare going to Evansville, that they may secure return tickets at one-third fare. The titles of nearly one hundred papers have been received for the programme, and the indications are that the meeting will be larger than any yet held by the Association. The problem confronting the members will be, not how to fill up the time of meeting, but how to stretch out the meeting sufficiently to accommodate all the papers. Perhaps fewer papers more leisurely discussed would be productive of better results in the end.

Dr. Ferdinand Hueppe, the author of the well-known "Methods of Bacterial Study," and who has for several years directed the bacterial department of Wesenius' celebrated laboratory in Wiesbaden, has been elected professor of hygiene in the University of Prague. The addition of Professor Hueppe to the working and teaching force of the University of Prague is an important feature in the growing attractiveness of Prague to American medical students who go to Europe for a few months of quiet study, and wish to avoid the overcrowded courses and distracting bustle of the larger medical centres.

The Hygiene of Tuberculosis.—At a recent meeting of the Paris Academy of Medicine, M. Villemin read a report of the Special Committee appointed by the Congress for the Study of Tuberculosis last year, which it was proposed to publish, with the object of instructing the laity as to the nature of the disease and the best means of avoiding contagion. The report calls attention to the fact that pulmonary phthisis is not the only form in which tuberculosis manifests itself, but that many cases of pleurisy, peritonitis, meningitis, and bone and joint diseases are often tuberculous. The report insists upon the contagiousness of the disease, and refers to the various ways in which the bacillus may gain entrance into the body. Since the sputa of phthisical patients usually contain the bacilli in large numbers, special care should be paid to the immediate destruction of all expectorated matters. The report also insists upon care in the matter of food, since milk, beef, and fowl are found not uncommonly to contain the bacilli. Milk should, therefore, be boiled before being given to children, and meat thoroughly cooked.

# Society Reports.

## BRITISH MEDICAL ASSOCIATION.

(Special Report for the THE MEDICAL RECORD.)

*Fifty-seventh Annual Meeting, held at Leeds, England, August* 13, 14, 15, *and* 16, 1889.

### TUESDAY, AUGUST 13TH—FIRST DAY.

DR. W. T. GAIRDNER, the retiring President, occupied the chair, and, after the reading and approval of the very voluminous minutes of the last meeting, delivered a short address. He said that it was now his duty to put an end to his official existence, and although it was, under the circumstances, a pleasant duty, he nevertheless wished to do it as briefly as possible. It was not desirable that a dying actor should remain too long on the stage. As President he might be said to be in a moribund condition, and to be handing on his torch, such as it was, to his successor, who did not, however, come out of the dark. Mr. Wheelhouse had been long before the Association, not only as one of the most active members of the profession in Leeds, but also as their representative on the General Medical Council. It was within the knowledge of those who had long been members of that Council that no man in it stood higher than did Mr. Wheelhouse in the opinion of that body. He was recognized as possessing tact, business talent, and every other quality that went to make a good Medical Councillor. He need not say that such a man, who added to those qualities high distinction as a surgeon, was eminently qualified to be the President of the Medical Association. He should himself resign the chair with feelings of warm gratitude toward all the members and officials of the Association for the way in which they had held up his hands during the period of his presidency.

MR. G. C. WHEELHOUSE, the President-elect, then took the Chair and made the following remarks: If in receiving the torch from Dr. Gairdner's hands he could carry the light still further before them, and could guide them aright, he should, of course, have the greatest possible pleasure in doing so; but he was not unaware of the fact that the task was a very difficult one. It might seem to those who came to the annual meetings, and only saw the happy, social side of the work, an easy thing; but those who knew anything of the hours spent in Council trying to guide the Association in its proper lines, and to do that which was right by every member of the Association, now numbering 13,900, were aware of the difficulty of the undertaking. He had not willingly accepted the honor they had done him in placing him in the chair, but he would, nevertheless, do all in his power to fulfil worthily the grave task which had been imposed upon him.

THE ANNUAL REPORT OF THE COUNCIL

was then read. In referring to the growth of the Association the report took the three meetings at Leeds as mileposts showing the rapid strides in membership. At the time of the first meeting at Leeds, in 1843, there were only about 1,600 members; in 1869 the Association again met in that city, and then numbered nearly 5,000; now, at the time of the third meeting in Leeds, the membership exceeded 13,000. The finances of the Association were in a very flourishing condition. The report closed with an expression of confidence in the ability of the editor of the *Journal* and in his devotion to the best interests of the association.

After some discussion the report was adopted. It was then resolved, on motion, that the members of the Royal College of Surgeons shall have a voice in the management of the college and in the election of its council.

A VOTE OF THANKS TO THE RETIRING PRESIDENT

was then moved and carried with great acclamation, and he was then elected Vice President for life

THE INEBRIATE'S LEGISLATION COMMITTEE

made a report in which it was stated that at length a permanent measure had been enacted for the benefit of inebriates. The members of the profession were coming very generally to the belief that inebriety was not always a crime, but was, in many cases, as clearly a disease as gout or insanity. This was encouraging, and the committee hoped that the good work already begun would be continued until public opinion had been educated to a point where it would be universally recognized that it was the duty of the Government to provide for the care and treatment of diseased inebriates.

Reports were also presented from the Committees on Scientific Grants, on Therapeutics, and on Collective Investigation. The last-named committee complained of a want of support from the profession at large, said that its inquiries were not responded to very generally, and suggested that it be allowed to lapse at the end of its official year in October next.

In the afternoon a special service was held in the parish church of Leeds, when the Bishop of Ripon preached to a crowded congregation on the subject of

DIVINITY AND MEDICINE.

He took for his text the words, "I have compassion on the multitude" (St. Matthew xv. 32). The conflicting thoughts and opinions of men were, he said, chiefly on the surface, but deep down there was union, and when petty differences were put aside all men were at last found to be of one mind in a house. There might be differences between religion and science, yet divines and physicians often walked side by side under the guidance of the principle of compassion. If divinity had had among the islands of the ocean a heroism like that of Father Damien, consecrating his life to disease and to death, medicine had had in their hospitals those brave men who had not hesitated to put their lips to the poison and draw death to themselves to save the child or the weak. Those things were their common heritage, for, after all, were they not expressions of the one great principle of compassion? They marched together thenceforward.

In the evening the members assembled in the Coliseum to listen to

THE PRESIDENT'S ADDRESS.

MR. WHEELHOUSE dwelt first upon

THE VARYING PROGRESS MADE BY MEDICINE

through the ages. Sometimes, he said, in the current of events her progress has been labored and slow; with halting and uncertain steps, with Arabian mythologists, astrologers, and such like visionaries as her companions, she has picked her way through gloomy times of mystery, uncertainty, and doubt. At times the light of truth has shone upon her path more brightly and has cheered her on her way; and with the Harveys, the Sydenhams, the Jenners, and the Hunters, the Dupuytrens, Laennecs, and Pasteurs of the world for her companions she has walked with firmer steps until at last she has become an acknowledged power, and stands forth as the companion of even the exact sciences. Each generation of her votaries, as it passes across the stage of the world's history, is henceforth bound to leave a mark behind it as its contribution to the sum of existence, and that mark must, in the aggregate, be the result of individual efforts. To some it is given to do great things, and to stand revealed by the unmistakable stamp of genius; to some, by more prolonged and patient effort, to leave an impress which, if it be not so brilliant, is yet equally fruitful and enduring; and to everyone of us, however humble may be the current of his life, it is permitted to make his mark, to add his little contribution to the total sum of a ceaseless progress, and to advance it or to hinder its advance.

He next referred to

THE COMPARATIVE ISOLATION OF PRACTITIONERS IN FORMER TIMES,

and to changes which had been brought in these later times by the wonderfully improved means for personal communication which have come by the advent of railways and the telegraph. The facilities for the spread of knowledge are now so increased that no discovery, in whatever part of the world it may be made, can wait long before becoming the general property of all.

The speaker then drew a picture of

THE GENERAL PRACTITIONER OF SEVENTY YEARS AGO.

He was usually a hard-working, industrious man, who thought little of bodily exertion, and who spent the greater part of his time in his saddle; a hard-thinking man, but one whose mental training had not been great, nor his education elaborate; whose opportunities for the acquisition of professional knowledge had been few and short. Knowledge and practice alike were purely empirical with him, and though he could treat disease with skill, and could, in most cases, give a good account of his war fare, it was purely by empirical means that he did it. His great panacea for all ailments was blood-letting, and his pocket was never unarmed with the all-potent lancet. He next turned to a consideration of

MEDICAL SCIENCE OF THE PRESENT DAY,

which was, he said, and the fact could not be gainsaid, far in advance of that of the beginning of the present century.

PUBLIC MEDICINE

was the next theme dwelt upon by the speaker, and which he defined as a science which seeks ever, even at the risk of its own extinction, to exterminate the causes of disease and death, and to eradicate from the world the very springs and sources from which they arise. It was now impossible for any epidemic to run riot as it did in former times. Can any work, he said, be nobler than this.

The subject of

MEDICAL EDUCATION AND EXAMINATIONS

was then considered at some length, and an ideal course of instruction for the medical student was sketched.

In concluding, the speaker said that, notwithstanding the infinitely greater knowledge and utility of the practitioner of the present day, there was a limit to his power —there was

ONE PLAGUE-SPOT

which even he will fail to conquer, and which will remain to fester, to kill its thousands, to maim, disfigure, and to sap the health of millions, of deserving and of undeserving alike, and, as the great curse of humanity, to baffle all our efforts to arrest the progress of disease, and to render them futile and abortive. This is the curse that steadily and vindictively pursues the track of licentiousness, of ungoverned passion, of hateful sensuality; and so long as human nature remains what it is, and is left in unbridled possession of the means of gratification, no ray of either light or hope will fall on that dark track. Some day men may have become sufficiently enlightened to submit to

NECESSARY LEGISLATION

and restrictions on this and cognate subjects; but, until they do, the foul stream will continue to meander hither and thither, and whithersoever it will through the world of life, will poison its springs, will wither even its fairest blooms, and destroy its richest fruits without selection and without mercy. By the cultivation of bacteriology and cognate sciences, by a deeper and more profound acquaintance with natural phenomena and laws, the time will come when the whole range of zymotic and exanthematous diseases will have been subdued and conquered; when the seeds of each will have been isolated, and so studied that their individuality will be recognizable; the soils in which they will grow and those in which they will lie sterile will be known and appreciated, and be brought under cultivation by the hands of the medical men of the day; and when, by the spread of sanitary science, the whole human race may be protected from their evil influences. It will not be in our day that these mighty triumphs will be won, but our successors will undoubtedly achieve them; and the time will certainly come when the kingdom of disease will be so closely narrowed down that only the necessary accompaniments of the changes and vicissitudes of natural laws, the evils attendant upon the wilful disobedience of those laws, the innumerable accidents to which life and limb must be forever liable, and the inherent defects and deficiencies in the harmonious working of the parts of a machine so exquisitely and delicately constructed as is the frail body which for a time we inhabit will be the only kingdom in which the professors of medicine and surgery will be called upon to exercise their sway. Then

THE VICTORY OF MEDICINE WILL BE COMPLETE,

and the day will have come when the world will be called upon to acknowledge that the labors of the physician and the surgeon, patient, enduring, untiring as they have been through all time, have not been in vain, and have reached their final consummation.

After a vote of thanks to the President had been moved and carried,

A PROTEST AGAINST THE MANAGEMENT OF THE "JOURNAL,"

signed by Sir Joseph Lister and others, was read. In this letter the writers threatened to resign from the Association if their protest was not heeded.

On motion of Mr. Lawson Tait, seconded by Dr. Robert Barnes, the steps taken by the Council for the management of the *Journal*, were approved, only one dissenting vote being recorded.

---

WEDNESDAY, AUGUST 14TH —SECOND DAY.

DR. BRIDGWATER moved that the Council be empowered to arrange for a place of meeting for 1890, and also to appoint a President elect. It was stated that no definite invitation had been received for this meeting.

DR. J. HUGHLINGS JACKSON then delivered the Address on Medicine (see p. 225) entitled

A COMPARATIVE STUDY OF DISEASES OF THE NERVOUS SYSTEM.

On motion of Dr. Eddison, seconded by Dr. Bristow, a vote of thanks was unanimously tendered Dr. Jackson for his address.

DR. BRIDGWATER, in a few well-chosen words, then announced the

AWARD OF THE STEWART PRIZE.

This prize had been founded by the late Dr. Alexander P. Stewart, who had left a sum of money, the interest of which was to be given each year to one who had done the best work of the year in the study of epidemic diseases. The prize for this year had been awarded to Dr. Klein for valuable researches on micro-organisms, and more particularly for work in connection with the etiology of scarlet fever.

DR. KLEIN, in a few words, returned thanks for the honor conferred upon him in the award of this prize, which he chose to regard as an acknowledgment of the services rendered to the science of medicine by bacteriology.

The President, Council, and Senate, gave a reception to the members of the Association at the Yorkshire College, and in the evening the President and the Local Examining Committee gave a conversazione in the municipal buildings.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, April 24, 1889.*

WILLIAM P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. EUGENE HODENPYL presented a series of specimens illustrating

### LESIONS AND MALFORMATIONS OF THE HEART.

Two hearts were shown in which there were chordæ tendineæ stretching across the cavity of the left ventricle. The speaker thought that this was not a very rare condition, and that it would be found more commonly than it is, were care used in opening the ventricle. In one of these cases a murmur was heard before death, but no particular importance was attached to it. He asked what had been the experience of the members present in regard to the production of murmurs by these chordæ. He had seen about fifteen cases of this sort recently, and in only one had the existence of a murmur been noted.

### DILATATION OF THE HEART WITH BUT SLIGHT HYPERTROPHY.

A young man had suffered all his life from symptoms of cardiac trouble. He also had Pott's disease of the spine. At the autopsy there was found an enormous dilatation of the left ventricle, with comparatively but a slight degree of hypertrophy. The aorta in this case was of very small size.

### ANEURISM OF THE MITRAL VALVE.

This heart was removed from the body of an old man who had been in the hospital for some time with symptoms of heart disease. He was found dead in bed one morning. At the autopsy the heart wall was found fatty throughout, and there was very marked thickening, with stenosis of the aortic valve. The aorta was atheromatous. An aneurism, about the size of a filbert, was found on the mitral valve.

### AN INCORRECT DIAGNOSIS OF AORTIC ANEURISM.

The specimen was removed from the body of a woman, forty-seven years of age, who had suffered from what was supposed to be an aneurism of the aorta. At the autopsy, however, no aneurism was found, there being only a very moderate degree of dilatation of the arch of the aorta. The aortic valves were thickened and stenosed, and one cusp was almost entirely obliterated. There was also a band of fibrous tissue stretching across the cavity of the left ventricle. On the surface of the lungs, beneath the pleura, were numerous little air-sacs.

### APOPLEXY OF THE OVARIES.

The same patient also had two fibroid tumors of the uterus, and the ovaries were rather peculiarly diseased. The surface of the organs was of a purplish color, and on section the cut surface was found to be almost jet-black mottled with white. The black color was found on examination to be due to the presence of altered blood, and the white spots were probably old corpora lutea.

### MULTIPLE ANEURISMS.

A man about fifty years of age was admitted to the hospital, suffering from an aneurism of the subclavian artery. The treatment consisted in ligation first of the carotid artery. The patient did well after this operation, and then the third part of the subclavian was ligated. This was not so successful, and the man had a secondary hemorrhage. Then the axillary artery was tied, but the patient died shortly afterward. A few days before death he suffered intense dyspnœa and had a severe cough. At the autopsy an explanation of the dyspnœa was found in the presence of a rather large aneurism of the innominate artery which pressed upon the trachea, narrowing its lumen. There was also a fusiform aneurism of the aorta, which had not been suspected during life.

DR. GEORGE R. LOCKWOOD, JR., said, in regard to the production of a murmur by chordæ tendineæ stretching across the ventricle, that such might very readily occur if the chordæ were attached to a papillary muscle, and were thus rendered tense. In the specimens shown by Dr. Hodenpyl, however, there was no such attachment; the cord would therefore become relaxed during systole, and consequently there could be no vibrations in it to cause a murmur.

DR. FRANK W. JACKSON thought it would be a very difficult matter to diagnose the presence of intra-ventricular bands. It was sometimes comparatively easy to diagnose an intra-ventricular murmur, and he had a patient now under observation with a heart murmur which he was confident was intra-ventricular; but it was a very different matter to determine the cause of this murmur, since several distinct conditions might occasion it.

DR. F. S. MCHALE presented a specimen showing

### TUBERCULOSIS OF THE PERICARDIUM.

It was removed from the body of a man forty-five years of age, who had had a cough for the past three years. Three weeks before admission to hospital, after exposure to the wet, he had an increase in the cough, which now became very severe, and pain over the entire length of the sternum. His face was drawn, flushed, and covered with perspiration. For a time there was some œdema of the leg, but this disappeared in about a week. At the autopsy no marked gross lesions were found anywhere except in the heart. This organ was enlarged, and the pericardium was irregularly thickened, and its cavity contained fibrin and pus. The inner surface of the parietal layer was studded with whitish nodules. Dr. Hodenpyl examined the specimen and reported that the new-growth was made up of small spheroidal, epithelioid, and giant cells. Examination of the kidneys revealed the presence of nephritis.

DR. HODENPYL said that it was important in these cases to note the condition of the bronchial and mediastinal glands. Weigert had lately made the assertion that the so-called tuberculosis of the pericardium was always primarily a tuberculosis of the mediastinal glands.

Dr. Hodenpyl then presented two specimens of

### TUBERCULAR PLEURISY AND PERICARDITIS.

The first specimen was from a man thirty-four years of age, who had been exposed four months before his death to cold and wet. He developed a cough, and then began to suffer from dyspnœa and loss of appetite. Physical examination revealed a pleuritic effusion on the right side. The patient was tapped several times, a large amount of bloody serum being drawn off each time. At the autopsy the pericardium was found completely adherent and thickened.

The second specimen was one apparently of primary tuberculosis of the pleura, with secondary affection of the pericardium. In this case the bronchial glands were examined and found to be tuberculous. On microscopical examination the sections showed almost the same appearances as those seen in Dr. McHale's case. The tubercles were somewhat cheesy, and contained large numbers of giant cells.

DR. WILLIAM P. NORTHRUP presented a specimen of

### ADHERENT PERICARDIUM

with dilatation and hypertrophy of the heart.

The patient was a male child, aged thirteen months. His only illness was double otorrhœa, so far as recorded. He was cross and fretful by seasons. Never had any contagious disease, unless possibly measles. Two days before death his respirations became rapid—60 per minute; the pulse was 160, while his temperature remained 99°. One day before death temperature was 100°, the extremities were cold, and the child screamed, apparently from pain, and seemed to be dying. He died without convulsions.

On autopsy, the body was found well nourished; brain normal. The heart was enlarged; weight 5 oz. 5 dr. The pericardium everywhere was adherent by loose bands which allowed moderate movement of the adjacent pericardial layers. The auricles and ventricles were dilated, and their walls were hypertrophied. The valves were normal, and the foramen ovale was closed. The great vessels were normal. The lungs were congested, œdematous, and flabby. The bronchial glands were moderately enlarged and dusky. Kidney, cortex pale; marking indistinct.

Dr. R. S. Freeman had looked up the literature of adherent pericardium in young children and had found the following cases reported. E. Cerf [1] reported forty-three cases of pericardial adhesion; of these the youngest was eight years of age. Samuel Wilks [2] reported six cases in early life; the youngest was nine years of age. A few cases in very early infancy are on record. A case was reported in Vienna where retraction over the apex was noticed on the eighth day, and at the autopsy fresh adhesions were found. Bednor found adhesions in a child of three months. Billard [3] makes the following note on the autopsy of a child, aged two days. There were "firm adhesions between layers of pericardium, producing belief that they were the product of former pericarditis developed during evolution of fœtus." This condition in a new-born child is also reported by Huetner.

Dr. Northrup presented a second specimen showing

ABSENCE OF THE SEPTUM AURICULORUM,

dilatation and hypertrophy of the heart, and acute exudative nephritis in a child aged thirteen and a half months. The child had always been "miserable" and irritable, but never sick. There was no history of scarlet fever or diphtheria, and the child was not a blue child.

On autopsy the heart was found very large, its common auricle being distended with dark clot, the walls of the auricle and ventricles were thickened. The ventricles were empty. There was a thin, membranous, crescentic rudiment, the only attempt at a septum auriculorum. The lungs were moderately congested, uniformly; no consolidation, no bronchitis; slight œdema.

Kidneys enlarged, cortex thickened, pale, markings varying from moderately distinct to indistinct and obliterated. The pyramids were congested, and in them and about their bases were masses of hemorrhage, and within the hemorrhagic masses pale spots. The striations and mottlings were found, under the microscope, to be formed of alternating masses of pus and hemorrhage. There were also hyaline casts and drops of cast matter within the tubes; also necrosis of the epithelium of many convoluted tubes. The urine from the bladder showed pus only. Other organs normal.

Four other specimens were presented, showing hernia in children. One of these specimens was of double congenital inguinal hernia. On the right side the cæcum and a few inches of the ileum were in the sac. On the left side the sac was empty. The opening easily admitted the end of the little finger.

Dr. Armstrong asked what was the experience of the members present in regard to the frequency of a patent foramen ovale. He had found it so often that he had almost ceased to look upon it as a rarity.

The President had seen it a number of times, and in many cases there had been no symptoms during life leading to a suspicion of the condition.

Dr. Ferguson said that some three years ago he had presented before the Society a series of specimens of patent foramen ovale. In every instance, however, there was a valve-like arrangement which effectually closed the opening in the septum, one part lapping over the other so that no direct opening existed. There was no cyanosis or other symptom during life pointing to the presence of an incomplete septum.

Dr. Armstrong said that in one of the cases of patent foramen ovale which he had seen there were four segments to the valve of the pulmonary artery. He had seen this condition several times.

Dr. H. S. Stearns presented a specimen of

TUMOR OF THE DURA MATER.

The tumor was of rather large size, and examination showed it to be a sarcoma. No extensive clinical history had been obtained, but it was stated that the man had been paralyzed a short time before death.

Dr. J. West Roosevelt presented some corrosion specimens, with remarks (see p. 237) upon

SIMPLE METHODS FOR MAKING CORROSION PREPARATIONS SHOWING THE GROSS ANATOMY OF LARGE VISCERA.

Dr. Freeborn exhibited a corrosion specimen, showing the terminal air-cells in the lung, which he had made several years ago. The injection material was celloidin. It was mounted in glycerine jelly, which the speaker thought was a very good medium for the celloidin. He had used ninety-eight per cent. alcohol to soften the celloidin and render it less brittle.

Dr. H. M. Biggs presented a specimen of

PATENT DUCTUS ARTERIOSUS.

The patient was a young man about twenty years of age, who was in Dr. Janeway's service at Bellevue Hospital, under treatment for pulmonary tuberculosis. There was a loud murmur heard in the second intercostal space on the left side, accompanied with a very marked thrill. A diagnosis of pulmonic stenosis was made. The patient had but little dyspnœa and no cyanosis. After death the lesions of chronic venous congestion were found, and there was seen to be a patent ductus arteriosus.

Dr. Biggs also showed a specimen of very pronounced

INTERSTITIAL MYOCARDITIS,

removed from the body of a man sixty years of age, who was under treatment for what was supposed to be asthma. He dropped dead one day while crossing the ward in the hospital. At the autopsy there was found to be advanced disease in the smaller arteries, and very marked myocarditis. There was commencing cardiac dilatation, and at one point the wall of the heart was exceedingly thin. There were also found one or two small calcareous plates on the tricuspid valve.

Dr. Frank Ferguson presented a specimen of

MILIARY ANEURISM

removed from a person who had died of cerebral apoplexy and also one of

PACHYMENINGITIS HÆMORRHAGICA

occurring in a man sixty years of age, who was supposed at the time of his death to be suffering from ordinary apoplexy.

A third specimen was one of

GIANT-CELL SARCOMA OF THE TONGUE.

It was removed by operation from a man aged forty years, who was thought, by some of the physicians who saw him, to be suffering from syphilitic ulceration of the tongue. The lesion began as a small ulcerated surface which gradually increased in depth, its edges becoming thicker, without any noticeable increase in area. Dr. Ferguson, when he first saw the case, made a diagnosis of epithelioma, and removed the growth. The lesion returned, however, with great rapidity. The glands also became enlarged, and upon removal were found to be sarcomatous.

Dr. Ferguson then presented a specimen showing

INTERSTITIAL MYOCARDITIS.

The patient was a boatman, thirty-nine years of age, of good family history, who had always been well up to within

[1] Bauer: Ziemssen, Handb. d. Spec. Path., vol. vi.
[2] Guy's Hospital Reports, vol. xvi., pp. 196–208.
[3] Billard: Diseases of Infants, p. 251. Philadelphia, 1850.

four months of his admission to the hospital. Then he began to suffer somewhat from dyspnœa, and this gradually grew worse until his death, which occurred six days after his entrance into the hospital. At the autopsy there was found to be an aneurism of the aorta which pressed upon the trachea, and the heart muscle was inflamed. The coronary arteries were perfectly normal, but the pneumogastric nerve was pressed upon by the aneurism, and it was to this that the speaker thought the myocarditis was in great measure due.

A fifth specimen was one apparently of

DOUBLE BLADDER.

It was removed from the body of a man who had given no symptoms of bladder trouble during life. The two portions of the bladder were connected by a very small opening. The second bladder was as large as the normal viscus, and was so situated that it made no pressure upon either of the ureters.

DR. BIGGS asked whether there were any stricture of the urethra, for the specimen looked to him like a distended ureter due to retention of urine, and not like an ordinary diverticulum of the bladder.

DR. FERGUSON replied that there was no stricture, and the prostate was not enlarged. He had never seen a case of diverticulum from pressure of the retained urine in which there was such a small opening.

DR. ROOSEVELT did not think that Dr. Ferguson's explanation of the occurrence of myocarditis was needed in the present instance. There was certainly disease of many of the vessels in the body, notwithstanding that the coronary arteries appeared to be normal, and it seemed hardly necessary to invoke the stretching of the pneumogastric nerve in explanation of the phenomenon. The pneumogastric nerve is often found to be pulled upon in cases in which no myocarditis is present. He asked what was the condition of the lungs.

DR. FERGUSON replied that the lungs presented the ordinary appearances seen in these organs in heart disease. In all the cases of aneurism that he had examined he had never seen a single one with interstitial myocarditis. He did not deny that the condition of the aorta in this case might have had something to do with the production of the myocarditis, but as to the coronary arteries, they were perfectly normal.

DR. BIGGS asked if Dr. Ferguson had ever before seen a giant-cell sarcoma arising from the tongue or in any tissue so far removed from bone.

DR. FERGUSON said that he never had. In this case the tumor commenced apparently in the mucous membrane of the tongue. When he first saw it, it was about the size of a bean. The giant cells were not reproduced, and the glands in the neck presented the appearances of a typical spindle-cell sarcoma.

DR. BIGGS said that he had recently seen a tubercular ulcer of the tongue in which there were very large and typical giant cells. In this case the lungs were tuberculous. Such a case as that reported by Dr. Ferguson must be extremely rare.

The Society then went into executive session.

---

*Stated Meeting, May* 8, 1889.

WM. P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. H. P. LOOMIS presented a specimen showing

CONGENITAL NARROWING OF THE COLON,

with extensive dilatation above the constricted portion. It was removed from the body of a woman, thirty-four years of age, who died at Bellevue Hospital, after a three weeks' sickness, from acute tubercular phthisis. The condition of the intestine was not suspected during life.

On opening the abdominal cavity the colon, as far as the splenic flexure, was seen to be enormously distended with gas. From a point just below the beginning of the descending portion of the colon to the anus, the intestine was collapsed, and in size not as large as a normal ileum. A careful examination of the abdominal contents showed nothing abnormal; there was no evidence of peritonitis, no bands of connective tissue, no adhesions, no new-growths, and no twisting of the intestine. On raising the small intestines the descending colon was seen to narrow in a funnel-shaped manner until, about four inches below the splenic flexure, it had reached about half its normal size.

Just below the funnel-shaped constriction was found a round, soft, fæcal mass, and scattered throughout the rest of the descending colon and the rectum similar masses were observed. On removing the intestines and making a careful examination, the colon was found perfectly normal, except that the lower portion of the colon and rectum were atrophied. Nothing was found within the intestine except fæces. Dr. Loomis said that he could account for the condition only by considering it congenital. The absence of any apparent cause for the condition, and the fact that the diminution in size was gradual and uniform, seemed to bear out this assumption.

Dr. Loomis also presented a second specimen, showing

A DIVERTICULUM FROM THE LOWER PORTION OF THE ILEUM.

The diverticulum was found at a distance of about twenty inches from the ileo-cæcal valve, and was of about the same diameter as the ileum, and eight inches in length. It presented all the appearances of the normal intestine, as regarded both its mucous membrane and muscular coat. In one case of this kind that the speaker had seen, the patient had died of typhoid fever, and the intestinal lesions of this disease were found in the diverticulum.

DR. J. C. PETERS said that quite a number of cases of intestinal diverticula would be found recorded in the first volume of the "Transactions" of the Society.

THE PRESIDENT said that in making autopsies on children he had often seen the upper portion of the colon enormously distended, while the lower part would be empty and contracted. He had never found any satisfactory explanation of this condition, but the specimen presented by Dr. Loomis reminded him of it. He asked how soon after death the autopsy was made.

DR. PRUDDEN said that in cases in which the lower portion of the colon is thrown out of use by reason of a stricture, there is very apt to be atrophy of the unused part. In such cases, however, there are some symptoms pointing to the condition present.

DR. LOOMIS said that the autopsy was made some twelve to eighteen hours after death. When he first saw the case it looked as though there were a constricting band, but none was found on examining the specimen more closely. The woman was sick in the hospital for three weeks before her death, but she presented no symptoms whatever indicative of any intestinal abnormality.

DR. H. J. BOLDT presented a specimen of

ADENOMA OF THE OVARY.

The patient, a woman in middle life, had suffered from pain about two years. Microscopical examination of the enlarged gland shows it to be in a state of adenomatous degeneration.

A second specimen was one of

FIBRO-MYOMA OF THE UTERUS.

It was impossible to enucleate the tumor, and in consequence the uterus was removed with it by the supra-vaginal method, and intra-peritoneal treatment of the stump was carried out.

GONORRHŒAL SALPINGITIS.

The specimen was removed from a woman who had been infected with gonorrhœa by her husband six months previously. Two months after the beginning of the trouble the left tube was found to be enlarged. No benefit was derived from the treatment employed, and the intense pain incapacitated her from attending to her house-

hold duties. Examination showed the uterus to be embedded in a mass of exudation. On opening the abdomen the tube was enucleated with great difficulty from the perimetric adhesions. The tube was enlarged, but apparently contained no pus, and on cutting into it before removal none escaped. The enlargement seemed to be due to interstitial inflammation.

The tube was, however, removed, because in case of suturing the wound the lumen might be permanently occluded, or, in the event of the sutures giving way, some of the products of gonorrhœal inflammation might escape into the peritoneal cavity. The opposite ovary was also diseased, having on its surface some small cysts; these were excised after Schroeder's method, which would allow the patient to continue in her generative functions. The three cases above reported made a good recovery.

In addition, Dr. Boldt said he desired to mention another case of rupture of a pyo-salpinx, successfully operated upon by his colleague, Dr. Von Ramdohr, a few hours after occurrence of the rupture, which took place during the night, necessitating operation at 3 A.M. His patient also made a good recovery.

### LYMPH NODES AND LYMPH NODULES.

DR. T. M. PRUDDEN referred to the new nomenclature in regard to the so-called lymphatic glands, and said that the Society might do much to promote its general adoption if the individual members would employ it. The so-called lymphatic glands are not glands at all, and should be called lymph nodes. There are other collections of lymph tissue, scattered about in various organs, which differ from the nodes in their small size, and in the fact that they are not distinct one from another and surrounded by a capsule, as are the nodes. These should be called lymph nodules. Then the term gland could be used where it belonged, and much confusion might be avoided. It was also a misnomer to apply the term solitary and agminated follicles to the collections of lymph tissue in the intestine. He hoped that the members of the Society would help along by the influence of their example the general adoption of this correct nomenclature.

The Society then went into executive session.

---

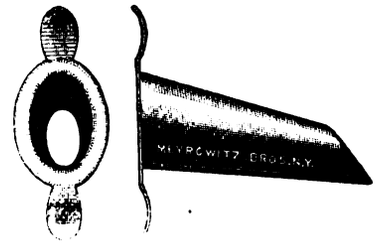
ENUCLEATION OF THE EYEBALL BY A NEW METHOD.—Dr. George M. Hamilton, of Ashland, Pa., writes: "In THE MEDICAL RECORD of May 11, 1889, I notice an article, credited to *The Lancet*, which gives the details of a method of enucleating the eyeball, as practised by Dr. Coppez, of St. John's Hospital, Brussels. It is one of the best methods in use; far simpler, as he claims, than those of Bonnet and Tillaux, both in regard to the instruments used and the manner of after-treatment, but it is by no means a new one. Dr. Biddle, of the State Hospital, Ashland, Pa., has been enucleating by this method for the last two or three years. The article says: 'The patient having been anæsthetized, and the eyelids separated by a speculum, a thread is passed transversely through the cornea by means of a curved needle; the ends of the thread are knotted and the loop held in the left hand. By traction on the loop the eye is drawn slightly forward, and with a curved scissors the conjunctiva is divided close to the corneal edge. The subconjunctival tissue is then torn through, and the tendons of the recti muscles come into view and are divided; next the oblique muscles, and finally the optic nerve.' This is almost identical with the operation performed here as far back as 1886. In order to more fully expose the insertions of the muscles, Dr. Biddle prefers to raise these structures with a blunt hook. This enables him to divide the tendons evenly, and get a better surface for an artificial eye. The danger of having the eye become flaccid, by the escape of contents of anterior chamber, can be reduced to a minimum by using a proportionately small needle and large thread, and introducing the needle at the corneo-sclerotic junction."

## New Instruments.

### A SPECULUM FOR APPLYING CAUSTICS TO THE DEEP STRUCTURES OF THE NASAL CAVITIES.

BY J. HERBERT CLAIBORNE, JR., M.D.,
NEW YORK.

THE accompanying cut represents a nasal speculum which I have had constructed for the purpose of making applications of caustics to the deep structures of the nose.



It will be seen that the instrument is a modification of Simrock's speculum. In front are two flanges for support by the index-finger and thumb when the instrument is inserted. There are two sizes of the instrument. The larger measures one inch and seven-eighths from tip to base. The diameter of the canal at the base is about six-eighths of an inch in height, and four-eighths of an inch in breadth. The edges of the truncated part of the cone are rounded, so that the mucous membrane may not be wounded when the instrument is inserted in the nose. The rounding of the edges is not correctly shown in the cut. The smaller speculum, while of the same length as the larger, just fits within it. In the case of very narrow nasal canals the horizontal diameter of the instrument can be diminished. The instruments are made of bright metal, but one of hard rubber can be used when the actual or galvano-cautery is employed. The manner of introducing it is as follows: The barrel having been greased with vaseline, the point of the nose is raised by the thumb of the disengaged hand; the thumb of the other hand is placed over the aperture at the base of the instrument, while the index and middle are hooked behind the flanges. The instrument is then pushed gently in, till, if need be, the whole barrel is sheathed in the nasal cavity. I find this instrument of peculiar value in making applications to the posterior tips of the inferior turbinated bones. Many surgeons use large aural specula for making applications, whether of fire or chemical caustics, to the deep structures of the nose. The use of these aural specula for the nose is attended by pain, even under the use of cocaine, and personal discomfort experienced from their use has suggested to me the instrument, the cut of which is herewith presented.

The instruments are made by Meyrowitz Brothers.

---

PATHOLOGICAL INFERIORITY OF THE LEFT SIDE OF THE HUMAN BODY.—When a unilateral lesion attacks any of the double organs of the human body, the left organ is more frequently affected than the right. Thus, obliterating arteritis attacks the left Sylvian artery, tuberculous infiltration occurs in the left apex, pneumonia in the left lung; calculous nephritis, or cyst of the kidney, attacks the left kidney; ovaritis and ovarian hyperæsthesia are observed in the left ovary; orchitis affects the left testicle, etc. M. Henry Duchenne tries to explain this fact by the greater activity of the right side of the body and the relative passive condition of the left side, which contains the heart. The mechanical activity of the right side determines nutritive activity. The mechanical passivity of the left side produces a kind of physiological mealiness, a pathological predisposition. Dr. Duchenne considers that the law of atavism may also explain the physiological inferiority of the left side of the body, for in ancient times, when hand-to-hand fights were always occurring, the activity of the right side of the body was constantly called into play.—*Medical Recorder.*

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 18, to August 24, 1889.*

BAILY, JOSEPH C., Lieutenant-Colonel and Surgeon, Medical Director Headquarters Department of Texas, San Antonio, Tex. Granted leave of absence for one month. S. O. 54, Headquarters Department of Texas, August 17, 1889.

BROWN, HARNEY E., Major and Surgeon. Died at Jackson Barracks, New Orleans, La., August 20, 1889.

POPE, BENJAMIN F., Major and Surgeon. Granted leave of absence for one month, with permission to apply through Division Headquarters for an extension of two months. Par. 7, S. O. 54, Department of Texas, August 17, 1889.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 24, 1889.*

SCOFIELD, W. K., Medical Inspector. Detached from the Lancaster.

HIBBETT, C. T., Passed Assistant Surgeon. Detached from the Lancaster.

WHITE, C. H., Medical Inspector. Ordered to the Pensacola.

HESLER, F. A., Passed Assistant Surgeon. Ordered to the Pensacola.

CURTIS, L. W., Passed Assistant Surgeon. Ordered to the New Hampshire.

JONES, W. H., Surgeon. Detached from the Pensacola, and placed on waiting orders.

WEDEKIND, L. VON, Assistant Surgeon. Detached from the New Hampshire, and ordered to the Pensacola.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 24, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 72 | 15 |
| Scarlet fever | 33 | 1 |
| Cerebro-spinal meningitis | 2 | 2 |
| Measles | 16 | 3 |
| Diphtheria | 71 | 12 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

A SPECIMEN ARMY MEDICAL BOARD EXAMINATION.—*Arithmetic.*—Time, forty-five minutes. 1. *a.* Multiply $17\frac{3}{8}$ by 13.37. *b.* Divide $4\frac{1}{8}$ by $2\frac{1}{8}$. 2. Define proportion in arithmetic. 3. If four grammes of morphia cost forty cents, what is the price per apothecaries' ounce and per avoirdupois ounce? 4. A owes B $1,000, to be paid in twelve days, and $500, to be paid in three months. If settled by one payment, when should this be made? 5. What is the cube root of .08769? 6. What is the air space of a ward 30 feet long, 18 feet feet wide, walls 13.5 feet in height, with six round columns 18 inches in diameter? 7. How can you ascertain the width of a river which you are unable to cross? 8. *a.* How is the value of an angle expressed? *b.* Name and illustrate by diagrams the principal forms of triangles. *Geography.*—Time, forty-five minutes. 1. Mention the sources and principal tributaries of the Missouri River. 2. Tell what you know of the physical geography of the peninsula of Florida. 3. What strait separates Asia and North America? What portions of land do the Straits of Magellan separate? 4. Explain the cause of the trade-winds. 5. Where and what is Samoa? 6. What are the principal mountain ranges of Europe, and where is each situated? 7. How is the State of Kentucky bounded? *History and Literature.*—Time, one hour. 1. What was the object of the crusades, and what the date [approximately] of the first? 2. What led to the earlier Arctic expeditions? 3. What were the most important decisive battles of the war of 1861–65, and who commanded the opposing armies? 4. Who were the allies at the battle of Waterloo? 5. What are the principal works of Chaucer, and in what century did he live? 6. Mention two or three of the early Italian authors and their principal works? 7. Who was Hawthorne and what did he write? Who wrote "Evangeline?" What did Prescott write? 8. What city was the scene of Homer's "Iliad," and where was it situated? *Chemistry.*—Time, one hour. 1. State the law of multiple proportions. 2. What is ozone and what are its properties? 3. Give the names and symbols of the non-metallic elements. 4. How is chlorine usually obtained in a free state? 5. What is the composition of phenol, and from what source is it obtained? 6. What is the source of the essential oils, and what are the chemical and physical properties? 7. What are the properties of hydrocyanic acid, and by what tests is it recognized? *Physics.*—Time, one hour. 1. In what direction is the pressure of the atmosphere most exerted? 2. What is the lowest point [Fahrenheit] registered by the mercurial thermometer? 3. Why is the light of a Bunsen burner non-luminous? 4. How do you determine the number of vibrations per second necessary to produce a given musical tone? 5. What do you understand by the emission theory of light, and what by the undulatory theory? 6. Mention and define one or more of the heat units. 7. Explain the construction and uses of the electro-magnet. *Hygiene.*—Time, two hours and a half. 1. What are the advantages and disadvantages of stoves as a means of heating? 2. What means would you adopt to prevent the spread of scarlet fever, and what to prevent the spread of typhoid? Give your reasons in each case. 3. What diseases have been most influenced by the construction of sewers in towns? 4. What is the proportion of $CO^2$ in the atmosphere of a sleeping apartment when a "close" odor from organic matter begins to be perceptible? 5. What disinfectants would you use during an epidemic of cholera, and how would you use them? 6. Mention some easy methods of testing the purity of milk. 7. What is the source of ammonia in impure water, and what is the most reliable test of its presence? 8. What is, under ordinary circumstances, a proper temperature for a sick-room or hospital ward? 9. What is the effect of alcohol on the excretion of pulmonary carbon dioxide? 10. Mention the death-rate of one or more of the principal cities in this country and in Europe. *Anatomy and Physiology.*—Time, three hours and a half. 1. Describe the surgical anatomy of the axillary artery, giving its origin, course, and relations in the different parts of its course: enumerate its branches and state their course and ultimate distribution. 2. State the parts cut through in a circular amputation at the middle of the thigh. 3. Name the arteries establishing the anastomoses around the knee-joint after ligature of the femoral artery. 4. Give the origin, relations, branches, and their final distributions, of the seventh cranial nerve, and state its functions. 5. Name the viscera: 1, covered by peritoneum; 2, partially invested by peritoneum; and 3, state what viscera have no peritoneal investment. *Physiology.*—1. Mention the different kinds of cartilage that exist in the human body; describe the peculiarities of structure that distinguish each variety, and state the purposes which each answers and where found. 2. What are the principal sources and modes of production of animal heat? Mention the circumstances causing variations in tempera-

ture of the human body; and state how the average temperature of the body is maintained and regulated. 3. By what means is the eye adjusted to distinct vision at different distances? 4. What are the functions of the sympathetic nervous system? Name the ganglia composing it, and state the location of each. 5. What is the total amount of the excreta, estimated as carbon and nitrogen, daily eliminated from the human body? and what amount and proportions of dry food are daily required for a healthy adult man of average height and weight? *Materia Medica and Therapeutics.*—Time, two hours and a half. 1. Give the source and composition of nux vomica, mention its preparations and doses of each; describe its physiological actions in (*a*) small, (*b*) full, and (*c*) toxic doses, and state the therapeutical indication for its use. 2. Give the officinal preparations of antimony, with doses of each; state the physiological actions of its principal salt, in (*a*) small, (*b*) larger, and (*c*) tonic doses, and mention the therapeutical indications for its use. 3. What is the active principle of calabar bean? State its physiological actions and mention the therapeutical indications for its use. 4. What is the source and composition of colchicum? Mention its preparations and doses of each; give its physiological actions and state the therapeutical indications for its use. 5. Name the fifteen officinal alkaloids. 6. State the principles upon which counter-irritants act, and mention the therapeutical indications for their use. *Practice and Pathology.*—Time, three hours and a half. 1. Give an account of the etiology and clinical history of diphtheria. 2. What are the symptoms of acute peritonitis? 3. Give the etiology of dilatation of the heart. 4. What are the principal causes of epilepsy? 5. Describe the treatment of typhoid fever. 6. How should you treat a case of delirium tremens? Give prescriptions in full. 7. Give an account of the pathology of tuberculosis. 8. Give an account of the pathology of Asiatic cholera. 9. Define eczema. 10. What are the principal diseases dependent on changes in the spinal cord? *Surgery.*—Time, three hours and a half. 1. What is the theory upon which antiseptic treatment in surgery is based, and how do the agents used modify the processes of inflammation? 2. Compare the effects of the principal agents used for producing general anæsthesia. 3. How is dislocation of the head of the femur on the dorsum ilii usually caused? What are its characteristic signs, and what is the *rationale* of its treatment by manipulation? 4. What are the causes, predisposing and exciting, of erysipelas? What circumstances influence prognosis? How would you treat a severe case? 5. What evidence would lead you to believe that the lung had been wounded in a penetrating wound of thorax, and how would you treat such a case? 6. In a case of gunshot fracture involving the ankle-joint what conditions liable to be present would influence your decision as to operative or conservative treatment? 7. Explain causation of organic stricture of urethra. What are its most frequent situations, and how does situation modify treatment? What diseased conditions may result from untreated urethral stricture? 8. What is the pathology of trachomatous conjunctivitis and its results when unrelieved? How would you treat a case? *Obstetrics and Diseases of Women and Children.*—Time, two hours and a half. 1. What symptoms indicate the existence of placenta prævia, and how would you treat such a complication occurring in labor? 2. What complications may arise in labor from abnormal conditions of the funis? What considerations guide you as to time of tying the funis? 3. Mention the chief conditions with which an ovarian tumor may be confounded and how a diagnosis is to be made. 4. What do you understand by subinvolution of the uterus? What are its causes and what its effects? 5. How would you diagnose a case of spasmodic catarrhal laryngitis from one of membranous laryngitis before expulsion of membrane? How would you treat a case of membranous laryngitis? 6. What is the pathology of essential infantile paralysis? What groups of muscles are most liable to be affected? What permanent results may be produced?

MATERNAL IMPRESSIONS.—Mr. Thomas Latham writes: "Some time in the year 1867 the wife of William Swindells, a farmer, residing near the village of Marple, Cheshire, England, gave birth to a child, she not having had one previously for fifteen years, and being then fifty-three years of age. The child when born had neither fingers nor thumb upon its right hand. Swindells and his wife resided with his brothers and cousins in a small hamlet off the main road. Some time before the birth of the child a stranger passed along the narrow cross-road which intersected the hamlet, and Mrs. S., glancing through the door, observed that the stranger had neither fingers nor thumb upon his right hand. Several of her relations also noticed the man's deformity as he passed the various houses, which were all built closely upon the narrow road. The double event of the birth of the child and its peculiar deformity was the talk of the villagers for miles around. I have myself often seen the child, which was a very healthy one, in my youthful rambles about the neighborhood. I could procure documentary evidence of the above facts in Marple village now if necessary."

THE RABIC COMEDY AT JARVILLE.—The commune of Jarville, in Lorraine, near Nancy, has recently enjoyed a hydrophobia scare of quite respectable proportions. The cause of all the commotion was a little black puppy, about two months old, that belonged to the proprietress of a public-house. The owner became ill, and, finding the puppy rather troublesome, made it over to a friend, who, in turn, transferred it to another, and so it passed through several hands in a short time. One of its owners was a drunken workman, who died from delirium tremens. The report soon spread that the man died from hydrophobia. The original owner, who had suffered for some time from cancer of the stomach, was so alarmed at this report that she took to her bed, and soon after had a final attack of hæmatemesis, to which she succumbed. Rumor assigned hydrophobia as the cause of her death also, and the town went wild. A large number of the inhabitants went to Paris, to the Pasteur Institute, at the expense of the commune, and after being inoculated returned home with minds at rest, and now propose to celebrate their deliverance by a *bal des enragés.* Thus ended what Dr. Linet, who chronicled the event, has called the rabic comedy of Jarville.

A COMPOUND LIQUORICE POWDER.—Mr. J. H. Fisher, in a paper recently read before the Pharmaceutical Society, said that he had some years ago prepared, at the suggestion of a medical practitioner, a compound liquorice powder which was in some respects an improvement on the pharmacopœial powder; it had a pleasanter taste, tart rather than sweet; it was more easily miscible with water, it was less liable to gripe; it was, however, a somewhat more powerful aperient, and had some diuretic and "refrigerant" properties. The formula is as follows: Senna, 2 parts; liquorice powder, 2 parts; fennel, 1 part; sublimed sulphur, 1 part; cream of tartar, 4 parts; sugar, 2 parts.—*British Medical Journal.*

CONSANGUINEOUS MARRIAGES.—A subscriber writes: "A short article in THE MEDICAL RECORD, No. 24, of June 15th, on 'Consanguineous Marriages,' attracted my attention. I would be grateful to you for the opinion of authorities on this subject as to the likelihood of diseased offspring or other injurious results from consanguineous marriages, and hope you will make it convenient to give space to this discussion in your journal."

CHEAP MEDICAL SERVICES.—A medical association has been formed in this city which advertises to furnish medical attendance to its subscribers for forty cents a month, and that all prescriptions for its subscribers will be filled by the leading pharmacists of the city for twenty cents for each prescription. In all probability the services and medicines are not even worth that.

### PARTIAL RESECTION OF THE HEAD OF THE FIRST METATARSAL BONE FOR HALLUX VALGUS.

#### A NEW METHOD OF AFTER-TREATMENT.

BY GEORGE R. FOWLER, M.D.,

SURGEON TO THE M. E. HOSPITAL AND TO ST. MARY'S HOSPITAL, BROOKLYN, N. Y.

THE most important deformity of the toes, as well as the most common, is that which is generally known as bunion, or hallux valgus. It consists essentially of an external deviation of the normal line of the great toe, or abducted contracture of the latter. Instead of forming a continuation in a nearly direct line of the first metatarsal bone, the great toe forms more or less of an angle with the latter, and lies in a position to cross the other toes, passing either above or below these, generally the latter.

The head of the metatarsal bone undergoes certain changes, these being due to two causes. First, the displaced phalanx, in its new position, produces increased pressure upon the external aspect of the head of the metatarsal bone, and, to a corresponding degree, lessens the pressure otherwise exerted upon the internal aspect of the same. The effect of this is to retard the growth of the former, and favor the growth of the latter. Second, certain changes, due to periosteal irritation, are often seen to be present. The first named results in a very decided projection of the metatarsal head, and as time goes on this may become more and more abnormally prominent, until at last a well-marked exostosis marks the site of junction of the phalanx with the metatarsal bone. The cartilaginous covering of the head of the metatarsal bone becomes more or less imperfect, and may disappear altogether. This occurs particularly in those cases in which the base of the phalanx becomes entirely displaced, and a new articular surface is formed for it upon the external lateral aspect of the metatarsal bone. Pressure upon the projecting metatarsal head leads to a callosity at that point, and not infrequently a bursa is developed in addition.

The disease is considered as being rather rare in young individuals. Nevertheless, I am convinced that it is not confined by any means to elderly persons. All three of the cases treated in the manner about to be described, occurred in the period of life between twenty and thirty years. No station in life seems to give immunity from the affection. I have not observed the disease more frequently among persons of a rheumatic or gouty diathesis; this is to some extent significant when the fact is taken into account that the latter is first apt to have its earliest and most decided expression in the very articulation under discussion.

I am inclined to attribute the occurrence of this deformity to the wearing of faulty-shaped shoes. Of all the shoes worn, that which is probably the most mischievous is the shape characterized by the pointed toe, with the point on a line with the middle of the foot. Any shoe which does not present a straight line upon its inner border tends to set up the initiatory changes which may result in the full development of this affection. Once the toe is forced from its proper relation with the metatarsal bone, the process of overgrowth of the internal portion of the head of the latter commences; this, conjoined with arrest of development or absorption through pressure upon the external portion of the head, leads to a rapid increase of the deformity. If the shoe be narrow at the site of the base of the toes, in addition to the pointed shape above alluded to, the pressure upon the projecting portion of the articulation will lead to the development of a callosity, and in some instances to a bursa. Inflammatory processes and their sequelæ may supervene in the latter, and it not infrequently happens that patients present themselves to the surgeon having one or more fistulous openings leading down to a suppurating bursal sac at the site of a hallux valgus.

There is another factor in the etiology of this deformity which should not be lost sight of. I refer to the influences exerted by a retraction of the proper extensor of the great toe, combined with the presence of an internal lateral ligament whose structure has been altered by pressure, and whose function of supporting the toe from undue abduction during extreme extension is more or less interfered with. It will be observed that the tendon of the extensor proprius pollicis does not cross the metatarso-phalangeal articulation on the line of the middle of the shaft of the phalanx, but rather toward its outer side. In some instances I have observed it lying in the slight hollow between the first and second of the metatarso-phalangeal joints. As the tendon passes forward from its point of emergence underneath the annular ligament, it is placed quite in the middle line of the dorsal surface of the foot for a part of its course; as it proceeds to its insertion in the last phalanx it lies quite upon the middle line of the shaft of the latter. The effect of this arrangement is to produce a movement of abduction of the toe when the action of the flexor proprius pollicis is brought into play. This abduction is opposed, in a voluntary manner, by the action of the flexor longus pollicis, which, unlike its opposing muscle, passes for almost its entire length along the middle line of the metatarsal bone and the phalanges of the great toe, and the abductor pollicis.[1] When these are not brought into play, the internal lateral ligament of the first metatarso-phalangeal articulation becomes the principal, and perhaps only, means of preventing the point of the great toe from becoming abducted. Should undue pressure, by means of a tight shoe, interfere with the integrity of the internal lateral ligament, and particularly if this be accompanied with an unusual tendency to extension caused by wearing high heels, a greater or less amount of abduction of the great toe, or hallux valgus, will be the result. The greater the deviation of the great toe from its normal line, the more the advantage gained by the extensor tendon is made manifest, until it almost appears as if retraction of this tendon, and this alone, is responsible for the deformity. But that this is a fallacy is proven by the fact that tenotomy of this structure in advanced cases does not result in restoration of the toe to its normal position.

Malgaigne was the first to call attention to the loss of support resulting from an attenuation or weakening of the internal lateral ligament, and considered this, together with muscular retraction or contraction, as being the essential factors in the production of the deform-

[1] It should be borne in mind that, in the surgical sense, this muscle is really an adductor. In the anatomical sense, the middle line of the foot itself is taken as the point from which abduction, and toward which adduction, takes place. Surgeons, however, select the median line of the body itself for the point. Hence the seemingly paradoxical nature of the statement that the abductor pollicis muscle opposes the abduction of the great toe.

ity. Nélaton expressed the opinion that hallux valgus depended upon a contractured condition of the tendon of the extensor proprius pollicis.

From the character and extent of the anatomical changes present in hallux valgus, and the extreme sensitiveness developed in connection therewith, which almost absolutely prohibits the application of orthopedic appliances with the view of restoring the toe to its proper alignment, the treatment of this affection by measures other than operative is exceedingly unsatisfactory. Of the operative means at our command may be mentioned, first, tenotomy of the tendon of the extensor proprius pollicis, with or without section of the external lateral ligament of the joint. These procedures were much practised and recommended by the older surgical writers, but have been practically abandoned of late years, owing to the very unpromising character of the final results obtained. Hüter, of Griefswald, proposed subperiosteal resection of the head of the metatarsal bone, and in this he was followed by the late Professor F. H. Hamilton, and A. Rose, of New York. In a certain number of cases, particularly those in which the joint has been invaded, and in which suppuration and caries are present, this is the only operation practicable. The objection to it is, however, that it shortens the inner margin of the foot unnecessarily, and by removing the inner support of the anterior extremity of the plantar arch, forces the weight of the body in walking upon the heads of the metatarsal bones of the other toes. These soon develop a painful condition, due to the crowding against the sole of the shoe. As before stated, this method of operating should be reserved for cases in which the joint has been invaded as a result of a suppurating bunion, or where caries has attacked the articulation.

A cuneiform osteotomy of the metatarsal bone was suggested and practised by Barker, an English surgeon. It is based upon a similar operation performed for the restoration of the symmetry of the limb in cases of genu-valgum. I have experience with this method in but a single case, and in that the result was far from satisfactory, for reasons to be alluded to further on. I do not think that this operation is destined to become a very popular one among surgeons.

The proposal to perform a partial resection, or to simply remove the overgrowth, or exostosis, of the internal portion of the articular head of the metatarsal bone, made by Reverdin, promises, in proper hands, and with rigid antisepsis and careful after-treatment, to be the operation above all others best calculated to achieve final favorable results. This procedure, however, like those of Barker and Hüter, is open to the objection that, in cases in which they have been heretofore carried out, the incision from which the joint is attacked has been made upon the inner side of the foot, directly opposite to the articulation. As a result of this, strictures are involved in the wound that are the site of a callosity or a bursa, or both, and the chances of failure in obtaining primary union in tissues of this character are very great. This occurred in the only case in which I attempted Barker's operation, and a long, tedious course of healing followed, accompanied by septic complications. Several attempts to follow the proposal of Hüter resulted similarly. Another objection, the validity of which is borne out by my experience in these cases, resides in the fact that, from the hyperæsthesia developed at this portion of the foot during the course of the disease, as well as the exposed location of the cicatrix, the result of these operations, the pressure of a shoe is not tolerated without considerable complaint on the part of the patient. It has been asserted that the pain, under these circumstances, is as great as before the operation.

Bearing these facts in mind, I had almost abandoned operative procedures for the relief of hallux valgus, when Petersen, of Kiel, published his article upon tuberculosis of the first metatarso-phalangeal articulation.[1] This surgeon proposed to attack the joint from its outer aspect, by an incision made between the great and adjoining toe, and extending through the entire thickness of that portion of the foot. By this method he declared the joint to be easily accessible, allowing the operator to thoroughly identify all diseased structures, and permitting of the retention of tissues not actually invaded by the tuberculous process. I at once realized that this incision, applied to the operation of hallux valgus, would do away with the objections which had deterred me from further attempts to effect a cure of this condition by the older methods. The following comprises the history of the first case thus operated upon, together with details of the steps of the operation itself, and a new plan of after-treatment designed to prevent relapse, and at the same time allow the patient to pursue daily duties without the necessity for the application of cumbersome apparatus, and the difficulties inseparable from attempts to maintain the latter in position.

On November 24, 1888, M. C. G——, aged twenty-five years, housewife by occupation, consulted me at the M. E. Hospital for relief of an excessively painful hallux valgus on either foot, of four years' standing. The deformity was very well marked, as shown in Fig. 1, taken from a tracing of the left foot. The patient believing the trouble to be due to rheumatism, had been treated with liniments and rest, and thus occasional temporary relief had been obtained.

Fig. 1.

On the day following her admission I performed the following operation: An incision was made from a point upon the dorsum of the foot, somewhat below the level of the head of the first metatarsal bone, and just outside of that portion of the tendon of the extensor brevis digitorum which goes to the great toe; this was continued to the bottom of the web between the first and great toes. A similar incision was made on the plantar surface of the foot, slightly to the outer side of the line of the tendon of the flexor longus pollicis. The intervening parts were divided through the whole thickness of the sole of the foot, so as to join these two incisions. The great toe was then strongly adducted, and the external lateral ligament divided, opening the joint. After freeing the soft parts from the neck of the first metatarsal bone with the handle of a scalpel, the phalanx was completely displaced. The great toe was adducted still further, until its inner border lay along the inner border of the foot, its point looking directly backward; the head and neck of the first metatarsal bone, together with a large exostosis constituting the "bunion," were thus freely exposed. The latter, together with the inner half of the articular surface of the former, were sawn off by an oblique cut, as shown by the dotted line, Fig. 2. The toe was then replaced in its normal position, and drainage provided for by a tube in the bottom of the gap. The soft parts were sutured; dressings of sublimate gauze and paper wool, and a splint, were applied to retain the toe in a straight position. The other foot was operated upon in the same manner. Union of the wound in the left foot was somewhat delayed by the occurrence of slight suppuration. In three weeks, however, the patient could walk comfortably, but was kept under observation until the end of the sixth week, when she was discharged from the hospital cured.

Fig. 2.

During the patient's sojourn in the hospital it was considered only necessary, in order to maintain the toe in its proper relations, to keep a straight splint of thin wood, well padded, applied to the inner border of each foot, to which the great toe was securely fastened. When, however, she was allowed to walk, and was about to be discharged, it became apparent that some retentive apparatus, less cumbersome in character than the latter, would be

[1] Langenbeck's Archives für Klinische Chirurgie, 1888.

necessary in order to facilitate free locomotion, and at the same time guard against the possibility of a relapse of the hallux valgus.

To accomplish this the following device was resorted to: In the first place, a stocking of rather more than ordinary width was chosen, and a double line of stitching run at the site of the interspace of the great and adjoining toes; by cutting accurately between the lines of stitching, a separate cot or receptacle was provided for the great toe, similar to the thumb portion of a mitten. Fig. 3 shows the stocking so arranged, drawn upon the foot. A shoe was then made, with a separate compartment located upon its inner border, and corresponding to the point at which the great toe should rest. In selecting a last for this shoe, care should be exercised in order to secure the so-called "common-sense" shape, *i.e.*, that which presents a straight inner edge of the foot (Fig. 4). The partition separating the compartment for the great toe from the balance of the front of the shoe, is made of two thicknesses of calfskin, and is secured in place in the following manner: The last is split, as shown in Fig. 5, and the pieces of calfskin from which the partition is to be formed are placed in position in the slot, a sufficient projection being left to pass through a slit in what is to be the inside sole of the shoe, in which latter location it is secured while still upon the last. The shoe and welt are then lasted in the ordinary manner, the reflected upper edges of the partition being stitched to the toe portion of the upper, and the shoe being arranged, in order to facilitate putting it on properly, to lace as low down as the site of the partition, which latter may be only just sufficiently deep to get a firm hold upon the toe, say about one-third the depth of the interdigital space. Fig. 6 shows the shoe, with one side of the upper cut away, in order to show the partition.[1]

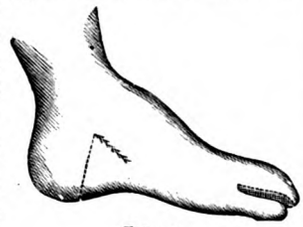

Fig. 3.

Fig. 4.

Fig. 5.

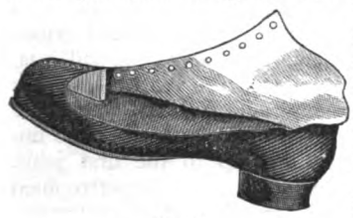

Fig. 6.

It is now nine months since the operation, and the patient declares that they are the most comfortable months she has enjoyed within her recollection. The partitioned shoe and glove-stocking give her not the slightest inconvenience. She walks several miles upon a stretch, whereas, prior to the operation, it was only by the most painful hobbling she was enabled to perform her household duties. Fig. 7 shows the present condition of her foot and the line of union of the wound.

Fig. 7.

The advantages of this method of operating are: 1st. Facility of reaching the articulation and determining the exact pathological changes present, and thereby determining the necessity or otherwise of removing the entire or only a portion of the articular extremity of the metatarsal bone. 2d. The incision is made through healthy structures, thereby, barring some error in the aseptic technique, insuring an uninterrupted and rapid course of healing. 3d. The external lateral ligament is divided, thus eliminating this as a possible hindrance to the reduction of the deformity. 4th. It renders practicable Reverdin's proposal to remove the exostosis when it exists; this latter being the best operation for the purpose of effecting a cure of hallux valgus. Plastic exudation or an organized blood-clot at once fills up the space made by the removal of the exostosis; this is not interfered with in its separative progress by possible infection through a wound from without, and adapts itself to the new location at once. 5th. If contracture of the extensor hallucis exists to an extent sufficient to prevent easy reduction, section of this tendon may be done through the same opening. 6th. It does not interfere with the attachments of the abductor pollicis, thereby favoring relapse from this cause. 7th. The resultant cicatrix is so situated as to be out of harm's way when the patient resumes the use of shoes. Hüter's operation, as well as that of section of the shaft of the metatarsal bone to facilitate reduction, may also be performed through the same wound.

Not among the least of the advantages of Reverdin's proposal to remove the existing exostoses in these cases, is that which relates to the preservation of the entire length of the metatarsal bone. This will be realized when it is remembered that the most important of the three points of support of the arch of the foot is formed by the head of these bones, and its preservation, whenever possible, is of the greatest importance. For this reason I prefer to so treat the deformity, where the conditions, as found when the articulation is exposed, will admit of it. Three cases have been treated by me in this manner, and the uniform success thus far achieved has been most flattering.

In a fourth case, one of the best-marked deformities of this kind I ever saw, and for the relief of which the patient had come to the hospital from a long distance with the expressed determination of having the member amputated, I found, upon exposing the head of the metatarsal bone, that no exostosis existed. A thick callosity and bursa, covering the stretched capsule and attenuated internal lateral ligament, occupied the site of the junction of the phalanx with the metatarsal bone. The articular cartilage was still intact, save here and there it was traversed by narrow, irregular grooves, giving the head of the bone a "worm-eaten" appearance. This is the only case coming under my observation having a distinct rheumatic history, and it partook of the character of an arthritis deformans. It was a question with me whether or not to remove the head of the bone, after Hüter, in this instance; but I finally decided to do so, and the immediate outcome of the case was all that could be desired. Sufficient time has not yet elapsed to enable me to judge of the functional result.

In a subsequent case of this character I would advise that partial section of the shaft of the metatarsal bone, through Petersen's incision, and just above its head, be made; a fracture at this point is then produced. The lower fragment can be placed at such an angle to the upper as to insure a proper alignment of the toe when brought into position. Or Barker's operation of cuneiform osteotomy may be done at this point. For all of these operations I consider the best instrument for making section of the bone, where the parts may be thoroughly cleared, to be a thin-bladed, fine-toothed saw.

---

Strychnine in the Alcohol Habit.—Dr. F. W. Allwright calls attention, in *The Lancet* of May 25, 1889, to the value of hypodermic injections of strychnine in dipsomania. He uses a solution of one grain in two hundred drops of water, giving of this five minims by one injection in the twenty-four hours. Hygienic and moral forces are also invoked in the management of his cases. He reports nine cases cured (?) in from ten days to three weeks. The drug causes, he says, a positive loathing for alcoholic drinks.

[1] The partition which is to occupy the interdigital space is unnecessarily deep in the drawing. If too deep, as the foot settles forward in the shoe as the result of wear, the bottom of the space will crowd against it, and produce discomfort. I am indebted to Mr. O'Gorman, the skilful maker of foot-wear, of Court Street, Brooklyn, for the intelligent manner in which my plan of arranging this partitioned shoe has been carried out.

## A CASE OF TRICUSPID STENOSIS, ASSOCIATED WITH AORTIC AND MITRAL LESIONS.

By C. M. HAY, M.D.,

ASSISTANT PHYSICIAN TO THE STATE INSANE ASYLUM, MORRIS PLAINS, N. J.; MEMBER OF THE MEDICO-LEGAL SOCIETY OF NEW YORK.

This rare form of cardiac lesion was found post mortem in a case admitted to my wards in this institution a short time ago, and the history, as far as can be obtained, is as follows:

Mary A. McW——, aged thirty-five, single, and by occupation a silk weaver. She was admitted April 25, 1889, and had been suffering with acute mania for three months prior to admission. These are all the facts I have been able to obtain of her previous history, and nothing could be ascertained of her family history. When admitted patient was much emaciated, unusually small in stature, and weighed about ninety pounds. She was wildly delirious, and her language and actions were typical of acute delirious mania. The condition of the woman made examination difficult, but it was noticed that she was slightly cyanosed all over the body, the coloration being most marked in face and extremities. The conjunctivæ were injected, but otherwise clear. In addition to the cyanosis, the skin was abnormally pigmented, and this was also most noticeable over the face and extremities. Physical examination the following day revealed normal lungs, some enlargement of hepatic and splenic dulness, and marked cardiac murmurs. The urine was scanty and high-colored, and on examination contained great excess of urates, a few red blood corpuscles, no casts, and no appreciable amount of albumen. The cardiac symptoms observed during repeated examinations may be detailed as follows: On inspection thorax was of normal contour. There was diffuse pulsation in the præcordia, extending over the epigastrium across to the right nipple line, and along the cervical vessels. The heart's action was seen to be very irregular. For a time the systole would be strong and transmit very distinct waves in the directions named, while, on account of the extreme emaciation, the heart could almost be outlined. After a minute or more of such action, the heart would suddenly begin to beat so rapidly that its pulsations could not be counted, and the adjacent tissues of the thorax presented an excited tremor. This usually lasted for a longer period of time than the slower and stronger contractions, but this alternation of rhythm was always observed. No distinct apex-beat could be felt, but the strongest impulses occurred in the fifth and sixth intercostal spaces in the parasternal line. There was a very coarse systolic thrill. Cardial dulness was somewhat increased in all directions. A double aortic and a double mitral murmur were heard, but a careful examination was impossible in the case. The murmurs were extremely loud; the systolic portions whistling and rather musical, and heard at any point over the thorax; while the diastolic or presystolic portions were almost equally high-pitched and shrill. The first murmur would frequently be broken by a pause, and when the heart's action became rapid and more irregular the confused mass of shrill notes, mingled with lower-pitched vibrations, defies description. Pulse very small, weak, irregular; at times not felt. The woman continued in acute mania, and the cyanosis grew gradually more marked during the two weeks following her admission. She then failed more rapidly, and on the seventeenth day became jaundiced, with a rise of temperature amounting to 102° F. On the nineteenth day there was marked jaundice, no fever, and the tip of the nose was perfectly black. On the twentieth day the nose became swollen and blebs formed; the cyanosis was much increased, and there was no pulse at either wrist, while the signs of a large præcordial effusion were evident. The existing dyspnœa became extreme, and the patient died on the twenty-first day after admission. At no time was there any œdema of the tissue other than in the nose (which was gangrenous before death); and, other than the pericordial effusion, no dropsy.

Post-mortem. This was performed six hours after death. Body extremely emaciated; nose and part of both cheeks swollen, black, and the cuticle was easily detached. No œdema elsewhere.

*Brain.*—Skull-cap of normal thickness. The dura mater was very adherent to it. There was considerable fluid in the arachnoid spaces, and the pia mater was opaque, thickened, and œdematous, the veins being especially well filled everywhere. On section of the brain substance the puncta vasculosa were unduly prominent, and the gray and white matter appeared equally congested. No other gross lesions were found.

*Lungs.*—The lungs were much congested, posteriorly presenting œdema and hypostasis. On section the lung structure seemed normal. Slight pleural adhesions at both apices. The stomach and intestines, with the uterus and tubes, were normal. The kidneys were enlarged, much congested, but capsule not adherent, and section showing their structure not perceptibly diseased.

*Liver and Spleen.*—The liver and spleen were both enlarged considerably, and both were markedly congested. In addition, the liver was curiously marked with grayish-white patches. The capsule was not adherent, however, over those, and section gave negative results.

*Heart.*—The pericardium was found filled with clear serum, the sac itself being normal. The arch of the aorta and great veins were of normal size and distribution. On opening the right heart white clots were found in the auricle and ventricle. The heart weighed thirteen ounces. The left ventricle was hypertrophied, while the wall of the right ventricle seemed unusually thin, and as the cavity of the ventricle was not enlarged the wall seemed actually atrophied. The muscular substance was normal, as was also the coronary arteries in their position, distribution, and walls. The aortic valves were fused together and formed a hard fibrous ring, into which the tip of the little finger could not be inserted. The united valves formed a cone with its apex toward the aorta. The endocardium was opaque and thickened from the aortic ring to the base of the anterior mitral segment, and also for one inch down over the interventricular septum. At the mitral orifice the valves, with their immediate attachments, had coalesced to form a cone pointing into the ventricle, with a narrow elliptical opening about one and a half centimetre in length by a half centimetre in width, and the little finger could just be inserted into it up to the first joint. The mitral papillary muscles were much hypertrophied and were directly attached to the edges of this opening, while the chordæ tendineæ were obliterated, having apparently united with each other and the valves to form the stenosis described. The left ventricle was not dilated, while the left auricle was much enlarged with thickened walls and dilated cavity.

The tricuspid orifice was markedly stenosed; the first two fingers could just with difficulty be inserted up to the first joint, and on examination only two valves could be found. These two were very much thickened and adherent to one another at their bases, and they were drawn considerably into the right ventricle from contraction of the chordæ tendineæ and papillary muscles. Where the edges of the two apparent valves met upon the side opposite the septum, there was a considerable thickening and fusion of the valve-tissues, and it seemed as if the missing valve had been chiefly involved in the pathological process, and had been nearly obliterated, only leaving a remnant of its tissue at the right juncture of the two remaining valves. But after a very careful examination of the specimen, I confess that I am unable to decide whether this was really so or whether the valve was not congenitally absent, while the two valves seen simply underwent subsequent sclerotic changes. The condition, as seen, resembled very strongly a small mitral orifice, with much thickened valves and contracted ring. The right ventricle, as has been stated, was not dilated, nor were its walls hypertrophied, but, on the contrary, seemed atrophied. The right auricle was very much hypertrophied and dilated,

the cavity being fully twice the normal size. It will be noted that both auricles were hypertrophied and dilated very much, while the ventricular cavities were normal in size, and the wall of the left ventricle was only moderately thickened. The pulmonary orifice, artery, and valves were normal. The aortic intima, for a distance of one inch from the valves, was thickened, but there were no calcareous deposits here or in any of the other lesions.

This case is interesting from the extent and situation of the lesions, the peculiar changes at the tricuspid orifice, and the symptoms observed during life, including the progressive cyanosis for such a long period of time, the acute maniacal mental condition for three and a half months prior to death, and the absence of œdema and dropsy, other than pericardial. The post mortem examination, as stated, revealed considerable venous congestion, and œdema of the brain and its membranes. The great infrequency of disease of the right auriculo-ventricular valves may be seen from the fact that, from 1851 to 1870, the post-mortem records of St. Mary's Hospital, London, gave but fourteen cases, and in all but one case the result was incompetency (Reynold's "System of Medicine," edition 1880, p. 658).

Dr. Bedford Fenwick (*Lancet*, January 22, 1881, p. 137) states that, since 1825, only forty-six cases of tricuspid stenosis have been recorded, and he concludes from a study of them that the greater number were due to changes after birth, while in all of the reported cases the mitral orifice was similarly affected, in nearly all the stenosis being greater at the mitral than at the right auriculo-ventricular orifice.

Dr. C. Hilton Fagge [1] says: "Indeed, although tricuspid stenosis in moderate degree is common enough when mitral stenosis is considerable or extreme, I am not aware that it is ever clinically met with apart from such an association;" while Roberts, "Practice of Medicine," says: "This condition is a mere curiosity, if it ever exists, or might possibly be due to endocarditis during intra-uterine life."

Dr. Hallam has recorded a case [2] in which the tricuspid orifice admitted only the tip of a forefinger.

In the frequently quoted case of Professor Gairdner, in which a diagnosis was made during life, the stenosis was caused by the pressure of a tumor growing from the auricle, and pressing upon the valve-segments.

Bramwell [3] states that acquired (non-congenital) tricuspid stenosis is far more common in females than in males, and also that, when the lesion is limited to the valves and ring, it is probably acquired, the congenital form being usually attended by other congenital defects of the heart and vessels. In this case, in the right heart the lesion was limited to the valves and their immediate attachments, and did not involve the endocardium of the right ventricle or auricle; while in the left ventricle the endocardium around both the aortic and mitral orifices was considerably thickened. The universal coincidence of mitral and tricuspid stenosis in cases of the latter affection is also illustrated in this case, while the superaddition of such extreme aortic narrowing adds much interest to the specimen. It would seem as if the stenosis of the mitral and tricuspid valves in part compensated the aortic lesion and distributed the work of the heart more evenly upon its chambers, and mainly upon the auricles, as shown by the marked hypertrophy and subsequent dilatation as seen post mortem. The fact of actual gangrene occurring in the nose before death certainly exemplifies the very slow failure of circulation, and the gradually increasing venous engorgement and peripheral stasis; while the absence of pulse at the wrist for several days previous is fully accounted for by the condition of the aortic valves, together with the coincident pericardial effusion and rapid failure of cardial power. The very marked cyanosis which the patient exhibited on admission, and which intensified until death, must have been due partly to the tricuspid lesion, which both tended to overfill the general venous circulation, and also prevented a sufficient amount of blood access to the lungs, so that the peripheral arterial capillaries both received an insufficient amount of arterial blood, while the venous capillaries suffered an increasing stasis. The chronicity of this condition is evidenced by the deeply pigmented condition of the skin.

## A SUCCESSFUL AND CONVENIENT METHOD OF TREATING PUERPERAL ECLAMPSIA.

By RICHARD COLE NEWTON, M.D.,
LATE CAPTAIN AND ASSISTANT SURGEON, U. S. A.

In this paper no discussion of the still unsettled question of the etiology of puerperal convulsions will be entered upon. I wish merely to discuss the principal methods of treatment and to lay before the profession a plan of treatment which has so far in this neighborhood served its purpose well.

It can scarcely be denied that eclampsia has hitherto constituted a part of the odia medicaiia, and that its treatment has not reflected much glory upon our art. Notwithstanding our utmost care in examining the urine of pregnant women, and our improved prophylaxis, a number of cases will occur in any obstetric practice. Moreover, either from accident or design, the urine of women about to lie in is not always sent to the doctor for examination. Add to these the small number of cases (percentage not yet determined) in which eclampsia occurs without ascertainable change in the urine, and the cases in which the patient may be attended by a midwife or other ignorant person, and in which a competent physician is only called when the woman is already in convulsions, and it is evident that anyone of us must hold himself in momentary readiness to treat eclampsia; with the assurance that his failure to save the patient will be widely known and pretty generally condemned, whereas his success will redound to his individual credit and will increase the prestige of our art.

Let us briefly review the more recent literature of our subject. That the disease is a frequent and dangerous one is well known. Professor Parvin, in a recent paper,[1] says that ninety-four deaths from eclampsia in about one hundred thousand labor cases were reported to the Philadelphia Board of Health in five years. He assumes that these ninety-four fatal cases were a third of the cases of eclampsia that occurred in Philadelphia in the period mentioned, which would give approximately one case of convulsions to every three hundred and thirty-three deliveries, and the high death-rate of thirty-three and one third per centum. Professor Thomas, in his lectures in my student days, gave the proportion of eclamptic cases as one to every four hundred and eighty-five pregnancies and the death-rate at from twenty-five to thirty per centum. The generally accepted figures are in close accord with Professor Thomas', *i.e.*, one case of eclampsia to every five hundred pregnancies and a mortality rate of thirty per centum. The number of cases of albuminuria in pregnancy seems, according to recent observers, to be much greater than was formerly supposed. However, with this aspect of the subject we will not at this time concern ourselves.

Now, from twenty-five to thirty per cent. of death is a high mortality rate from any acute disease; higher, probably, than that of any other acute disease that afflicts the good people of this latitude and longitude. It is not to be wondered at that childbed convulsions are intensely dreaded by the profession and the laity.

Much has been written on this important subject and considerable progress has been made in unravelling the mysteries which surround the still somewhat obscure questions of its etiology and therapy.

As to the principal modes of treatment, I think we

[1] Hirst's American System of Obstetrics, vol. ii., p. 75.

may justly say that they are four in number: 1, Chloroform to control the spasms, often combined with other medication, as, *e.g.*, drastic carthartics; 2, morphine, hypodermatically; 3, venesection; and, 4, the induction of labor. Probably a fifth, viz., the administration of veratrum viride, should be added. Of course, there are many and various ways of treating eclampsia, but I think that a large majority of physicians in these days place their chief reliance upon one of the means mentioned in our list. There has always seemed to be a disposition to adopt one method to quiet the spasms, and to supplement its action by another, to alter or eliminate the morbific material from the system. If chloroform is given, cathartics, sudorifics, or diuretics seem to follow. If the patient be bled, she seems to be also subjected to hot baths or purging. Doubtless, if labor is to be brought on, the spasms are meanwhile controlled by chloroform, etc. It is this dual indication which, I believe (with our present light), it is necessary to follow out if we wish to successfully cope with eclampsia.

A few years ago pilocarpine was brought forward as the best and most scientific drug with which to combat this disease. I understand that it is now recommended to the students in the Harvard University Medical School as decidedly our best means of treatment. Still, a number of cases in which jaborandi or its alkaloid have failed have been reported. And as the drug so often acts uncertainly in general medicine it seems doubtful whether it will ever be looked upon with general favor in eclampsia.

Professor Parvin [1] speaks of chloral with some favor; and there seems little doubt that the fearless exhibition of this drug has, in a number of reported cases, given excellent results. Professor Byford praises colchicum in eclampsia.[2] Oxygen has been tried and spoken well of.[3] Of course, galvanism has not been left without a champion.[4]

Not to take up too much space with the consideration of these lesser known remedies, let us confine our remarks to the five principal methods of treatment mentioned above.

First, chloroform is no doubt the most widely known of the remedies in eclampsia. A short list of the distinguished men who have advocated the drug would comprise some of the brightest names in medicine. It would, therefore, be out of place for me to cry down this valuable and potent agent; neither is it necessary here to go into a detailed discussion of its merits. An unsurmountable objection to its use is the amount of time which the physician must give to one patient if he uses chloroform for eclampsia. Professor Thomas used to say that, to be effectual, the remedy must be kept up for from twenty-four to forty-eight hours. As no conscientious physician would like to intrust the administration of chloroform to a nurse, he must, in case he gives it in puerperal convulsions, remain at the bedside for one or two whole days and nights, and maybe longer.

In may cases this must be impracticable, and it can never be convenient to oneself nor just to one's other patients. Had the treatment by chloroform been generally satisfactory, so many substitutes for it would not have been brought forward.

As to morphine in eclampsia, two or three cases which have occurred in this neighborhood tend to confirm the common impression of its danger. Certain promising young matrons, although fully brought under the influence of this drug, lost their lives; and two of our practitioners have told me that, although once strongly in favor of morphine in the convulsions of childbed, they have now abandoned its use. In the literature of the subject many diverse opinions prevail. Professor Byford [5] strongly condemns it. Rosenthal [6] says that the opiate treatment gives good results, especially after delivery. Professor Thomas would seem to agree with Rosenthal. A writer in the *Pacific Medical and Surgical Journal* recommends one and one-half grain of morphine hypodermatically, and says that he is convinced that twice the quantity might be administered once. Almost the latest reference [1] to the treatment of this disease, that has met my eye, states that Veit, after using other methods, has been led to rely upon morphine. His initial dose is three-fifths of a grain hypodermatically, followed by half as much when required. He adds: "It is generally necessary to give from one and one-fifth to three grains in from four to seven hours. . . . For the renal complications hot baths followed by packs are best; pilocarpine favors pulmonary œdema.

Theoretically these large doses of morphine must do harm by locking up the secretions. It would seem that such therapy is on a par with the conduct of a person who, after discovering a fire on his premises, should take great care to exclude the firemen by locking his door and throwing away the key. This view receives strength from the fact that after delivery the secretions (markedly that of the kidneys) rapidly re-establish themselves, and that morphine can then be borne. However, in Galobin's tables [2] only eight per cent. of the women seized with convulsions post-partum died; so that any treatment would have to be very bad to show a high mortality rate in such cases.

Furthermore, the doses of morphine recommended in eclampsia are, to say the least, startling to a quiet mind.

The question of bleeding has received a great deal of attention. Formerly it seems to have been nearly universally practised, and it has powerful advocates to-day. Dr. Michener and others published [3] a brochure four or five years ago, containing forty-four cases of eclampsia, all that they could collect that had occurred in their county (Chester County, Pa.). They unreservedly advocated venesection. In the Medical and Chirurgical Faculty of Maryland [4] several speakers were enthusiastic in favor of bleeding in these cases.

A Dr. Darvon, of New York State,[5] stated in a medical meeting that he and his father had successfully bled their eclamptic patients for ninety-two years. Professor Thomas advised it in a few sthenic subjects with great vascular tension and plethora. Professor Parvin [6] speaks more favorably of venesection in selected cases than of any other one method. Professor Thomas,[7] however, modified his advocacy of this procedure by stating that phlebotomy is a method inferior to chloroform, more unreliable, and dangerous. I presume that he still holds this view. Professor C. Braun [8] gave up venesection years ago, and quotes other authorities who have done likewise. At best, with our modern ideas, bleeding is revolting and frightful to the patient if conscious, and certainly to the friends. It removes some of the vital fluid from a patient who, if she comes out of her spasms, has probably a long convalescence before her. Neither is it always efficacious; a number of failures having been reported in cases of convulsions treated by bleeding. It might tide the patient over some uncontrollable spasms, especially where there seemed to be sufficient vascular tension to threaten apoplexy. Although this latter contingency is mentioned by Trousseau, its occurrence must be quite rare.

The induction of premature labor as a means of curing or preventing eclampsia seems to be growing in favor among the profession in this country. At a meeting of the American Association of Obstetricians and Gynecologists held in Washington in September, 1888, the consensus of opinion seemed to be wellnigh unanimous in favor of this method of treatment.

Professor Thomas used to say that for the purposes

[8] Braun: On Puerperal Convulsions.

of treatment he divided his pregnant patients who showed albumen in the urine into three classes—slight, medium, and grave. In the latter class he always advised that labor be brought on at the eighth month of gestation. A number of cases are reported, some successful and others not. One writer [1] saved four out of six women in whom he produced premature labor.

The induction of premature labor, or of abortion, is always a grave undertaking. Perhaps we are apt to lose sight of its gravity. Nature ever resents this interference with her laws. She will, and frequently does, terminate a gestation whenever such a course seems to be indicated for the welfare of the mother, as, for example, in uterine displacements, fevers, cholera, etc, and also where the fœtus if viable would not probably ever develop into a healthy child, as, for example, in syphilis, scurvy, Bright's disease, etc. The well-known comparative immunity of pregnant and lying-in women from epidemic and endemic diseases, their almost miraculous recoveries from post-partum hemorrhages, complicated labors, etc., all point to the peculiar and fostering care with which nature regards her pregnant daughters. Just in proportion as extaordinary safeguards are thrown about those women who fulfil the law of their nature and do their share toward propagating the race, just so far does nature resent our interference with gestation. It is no light matter to bring on labor under any circumstances. Witness the high mortality rates in criminal abortions, no matter how skilfully these comparatively simple operations may be performed. Witness the broken health and lifetime of suffering which so often follow. Any clown can bring on a miscarriage, but no human agency can repair the damage he will probably inflict upon the unfortunate woman. Professor Mc Lane used to tell us that he would rather any one of his patients would have two babies at term than abort once. Professor Braun [2] quaintly observes that he has frequently seen premature labor brought on for hyperemesis fatal, but he has never seen hyperemesis fatal.

My friend Dr. Love, of Montclair, tried bleeding in his eclamptic cases. His success was but indifferent. He then tried the induction of labor, and declares that the latter method was worse than the former, since by bleeding he did save some cases, whereas when he brought on labor he lost nearly every case that he had.

Leaving the consideration of the veratrum viride treatment for a moment, I think that I have indicated that every means so far generally employed to combat this terrific disorder has frequently failed. So far as I know, it is not claimed that the mortality rate for any large number of cases has been kept below twenty-five per centum by any mode of treatment. Dr. Breus [3] reports twenty-two cases treated with hot baths, with a mortality of only two (ten per cent.). Dr. C. Braun reports sixteen cases successfully treated with chloroform and acids. Nitro-glycerine has proved a valuable adjuvant in a few reported cases. Now, as the mortality has not apparently been greatly altered by the various (and sometimes totally different) modes of treatment in vogue, it seems fair to assume that a large percentage of cases would recover without treatment. Galobin [4] gives some interesting figures, as follows:

> Average mortality at Guy's Charity, 25 per cent.
> Of those attacked before labor, 50 per cent. perished.
> Of those attacked during labor, 25 per cent. perished.
> Of those attacked after labor, 8 per cent. perished.

Professor Braun remarks, in his excellent monograph, that of those seized with convulsions before labor few recovered.

Charpentier [5] gives some figures showing the mortality as influenced by the number of seizures:

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Of 45 | women | who | had | from 1 to 10 | convulsions, | 25 | per cent. | died. |
| " 31 | " | " | " | 10 to 20 | " | 33 | " | " |
| " 24 | " | " | " | 21 to 50 | " | 50 | " | " |

There would appear to be a wide and only partially cultivated field of study before us in puerperal convulsions. However, let us hasten on and take up our last division of the treatment, viz., that by veratrum viride.

This drug has enjoyed a checkered career since it was so boldly thrust upon the profession by Dr. Norwood in 1850. Good authorities seem to be still disputing about its value in pneumonia. In some other diseases, as, *e.g.*, diarrhœa and dysentery, its value does not seem to have been as yet well studied. Professor Fordyce Barker is said to have suggested its use in eclampsia forty years ago. Since that day it has never seemed to lack a champion as our best treatment in this disease. Various Brooklyn physicians have spoken highly of it, and I fancy that it is gradually gaining ground. I notice that it is favorably mentioned in the last "Year Book of Treatment," and in Hirst's "American System of Obstetrics" (just published). However, the profession at large do not yet seem to trust this remedy, which is now suffering unmerited obloquy—the natural result of undue praise.

Twenty-eight years ago Dr. Cutler, of Jersey City, stated in the New Jersey Academy of Medicine that he had been in practice twenty-five years, and that during that time he had seen on an average eight cases of puerperal convulsions a year, in his own practice and in consultation, and that he had never lost a case, and that in treating this complaint he relied upon veratrum viride. Dr. Love was present and heard these remarks. Shortly afterward the late Dr. Isaac Nichols, of Newark, called the doctor's attention to benzoic acid, and suggested its use in the albuminuria of pregnancy. My friend put the hints dropped by these older men (at that time eminent in this State) together, and concluded to treat his next case of eclampsia with veratrum viride and benzoic acid. This was many years ago, and Dr. Love has seen no reason to alter his treatment. He has had in all twenty-three cases and he reports twenty-three recoveries.

In the stirring up of dry bones and scattering of ancient records which moving one's office after many years' occupancy causes, the notes of these individual cases were lost or mislaid. But a dozen or more of the women are now residing in this neighborhood, and can be seen and interviewed. Case No. 23 has occurred since this writing was begun. She is a primipara, twenty-three years of age. Her urine was highly albuminuric on April 30th. In spite of treatment, by May 15th her water had diminished to less than five ounces per diem. It resembled pea-soup in appearance, and when boiled with nitric acid it promptly solidified. She then fell into convulsions and had six in twenty-four hours. During this time she remained totally unconscious. As it was difficult to make her swallow, and as the veratrum viride exhibited per orem was vomited, eight minims of Norwood's tincture were given hypodermatically, which also produced emesis. This amount was, however, injected under the skin every hour until five or six doses had been given. The benzoic acid was also given every four hours. I saw this patient afterward myself, and made frequent examinations of the urine. Microscopically, tube-casts and renal epithelium were noted. About three weeks after the convulsions labor came on of itself and a child was born, which lived a month and died in convulsions. The mother made a good recovery.

Dr. Love says that, in his experience, within twenty-one days after the first spasm labor will come on, and that the fœtus is generally dead.

Only two children in his twenty-three cases survived. In the case just given he tried nitro-glycerine as a help to eliminate the materies morbi, but had to give it up on account of the headache it caused.

His plan of treatment has been as follows: Give three drops of Norwood's tincture (a freshly prepared portion) and repeat in an hour; then two drops every hour or two until the patient experiences a cord-like feeling in the neck. If the nurse be not sufficiently intelligent or conscientious, the physician must give the veratrum viride

himself. The benzoic acid is given in the following prescription, which is taken from Ellis' "Formulary," and is No. 120 in that collection of recipes:

℞. Acidi benzoici ..... ʒ ij.
Potass. bicarb..... ..... ℥ ss.
Spts. ether nit..... fl. ℥ j.
Spts. mendereri..... fl. ℥ ij.
Syr. limonis.....q. s. ad fl. ʒ vj.
M. Sig.: ℥ ss. q. 4 hrs.

This must be mixed with some care, but any competent pharmacist can do it. It forms a rather unpleasant dose.

All I claim for Dr. Love is a happy and partly original combination of well-known remedies. No one else has, so far as I know, reported twenty-three successful cases without a break. Professor Braun's sixteen cases, treated with chloroform and acids, is the next best showing that I have found. Dr. Staples, of Dubuque,[1] reported uniform success for nine years with veratrum viride and aconite hypodermatically. Number of recoveries not stated.

Under Dr. Love's treatment the infants can scarcely be said to flourish. Under any treatment it appears that one-half of them die; and of those born alive, as Tyler Smith points out, a number will die of convulsions (Dr. Smith calls them uræmic convulsions). If, then, there is more probability that the child will die than live, we would hardly be justified in abandoning a course of treatment promising the best chance for the mother's life because some other may give a higher per centum of living children. Löhlin's, Winkel's, and Hecker's reported cases[2] show that from seventy-seven to eighty-five per cent. of the women were primiparæ; and all the best authorities agree in saying that a woman will probably not suffer from eclampsia twice. Therefore, according to our view, it is inexpedient and even reprehensible to weigh the child's chances for life against the mother's when we know that the latter, if she come out of her spasms, will probably live to bear healthy children.

This plan of treatment is the result of nearly a lifetime of thought and observation. In Dr. Love's hands it has not failed once in many years. It is convenient and easy to administer, and absolutely harmless in competent hands. It is freely offered to the profession with the hope that it will be found as successful in other hands as it has been in those of my esteemed friend, and that it may prove another trusty weapon in our armamentarium.

MONTCLAIR, N. J., August 6, 1889.

## THE TREATMENT OF PNEUMONIA BY TEPID BATHS.[3]

BY GEORGE N. KREIDER, A.B., M.D.,

SPRINGFIELD, ILL.

DURING the past few years much has been written about the alarming mortality of pneumonia. Men whose wide experience has extended over a long period of years affirm that the death-rate is much higher under the present accepted modes of treatment than it was forty years ago, when the pathology of the disease was almost unknown. It would hardly seem that our therapeutics of pneumonia is commensurate with our knowledge of its etiology and pathology. Some endeavor to explain this increased death-rate by supposing that a change in the character of the disease has occurred in the last half-century, while others claim that the statistics are made more unfavorable by the fact that a larger number of poorly nourished and dissipated persons are now treated in the large city hospitals where these comparisons have been made. Whatever may be the explanation, it remains true that the mortality-rate is extremely, and I believe unnecessarily, high. The high mortality-rate of pneumonia and typhoid fever in America is the medical opprobrium of our country. Dr. Osler says death in this disease is most frequently due to high temperature and heart failure, and it is against these very grave symptoms that our present treatment is least effective. The same statement might be made, and with equal truth, concerning typhoid fever. The newer antipyretics antipyrin and antifebrin have their place, and if used with proper precautions may render material assistance; but, used in a routine and indiscriminate manner, they are capable of doing more harm than good. They may enable us to reduce the height of the temperature, but are not lessening to any great extent the mortality of this disease. Too frequently they depress the heart's action and disturb the stomach, and thus cause complications of the gravest nature by preventing the patients' taking a sufficient quantity of nourishment, and by impeding the circulation of blood through the lungs. After careful consideration, and influenced by the successful use of the ice-coil in my practice, in the treatment of typhoid and puerperal fever, I came to the conclusion some time since that a change in my method of treating pneumonia was desirable. Relying upon the statements of well-known German authorities, I decided to make a fair and impartial trial of tepid baths in grave cases. The employment of these means is so contrary to all our American teachings and traditions that it is only in the last six months that I have gained sufficient courage to employ them. So great is the fear of cold in the minds of both the laity and the profession that it is doubtful whether I would have been permitted to make the experiment earlier in my professional career. For this reason the number of cases which I am able to relate in support of my views is not as great as would be desirable. However, I believe that a careful clinical study of a few cases is quite as valuable in proving principles as tables embracing an indefinite number can be. Modern investigation has certainly proven that micro-organisms of some kind, and not colds, are the immediate cause of this disease, and in the light of this discovery all mistaken prejudice against baths and cold applications must fall to the ground. Pneumonia is essentially a fever, which should be treated, as far as its effects on the respiration, temperature, heart, and skin are concerned, like any other fever. I do not pretend to say that every case of pneumonia should be treated by baths. Strümpell wisely says it is disadvantageous, if not injurious, to give a patient baths if the disease is progressing favorably, for almost every bath has some disagreeable features which should be avoided if possible. All these disagreeable features vanish in a bad case. The possibility of the necessity for baths should be had in mind on assuming charge of every case of pneumonia, and arrangements made accordingly. A portable bath-tub should be in storage from which it can be taken at a moment's notice. The dealer of whom I procure the tubs rents them out at a reasonable figure, and is easy of access day and night. A portable tub can be placed by the bedside and the patient lowered into it without the least physical exertion on his part. The patient should be placed on a single bedstead, with low head- and foot-pieces, for convenience in handling sponges and towels; dry sheets and blankets should be on hand in abundance for use during and after the bath. After the tub is once properly filled very little more disturbance is necessary, since the water will retain its heat for a long time and one or two buckets of hot water will bring it to the required temperature. The reasons for resorting to the treatment should be fully explained to the relatives, and their hearty co-operation secured. I have thus far found little opposition where this treatment was proposed, and this was usually volunteered by some officious neighbor whose medical attendant "never did such a thing." The physician himself must superintend and assist in giving the baths. Especially is this the case in children, whose expressions of fear will often influence the parents to the detriment of the treatment.

I have used baths in the treatment of six cases. All have not been successful, but in none were any bad symp-

[1] THE MEDICAL RECORD, February 21, 1880.
[2] American System of Obstetrics.
[3] A paper read at the Thirty-ninth Annual Meeting of the Illinois State Medical Society.

toms caused by the bath; on the contrary, in every case the patient came out of the tub refreshed and improved, for the time at least. The first case treated was Mrs. F. W. T——, aged thirty-five, seen with Dr. Dresser in the second week of puerperal fever, and with strength reduced by that disease. She developed at this time catarrhal pneumonia of the right lung, beginning with a severe chill, pain in the side, and elevation of temperature, pulse, and respiration. She was treated with antipyretics, stimulants, and expectorants for six days, without very apparent benefit. Matters had seemingly reached a critical point. The pulse and temperature remained elevated, and little or no material was raised from the lung. There was coma vigil, muttering delirium, and picking at the bedclothes. I finally urged, as a last resort, the employment of a bath, to which my colleague finally consented. To give it we were obliged to carry the patient to another room and immerse her in a stationary tub, which was only accessible from one side. This increased the labor of the treatment a great deal, and minimized its benefits. The temperature of the baths was 98° F.; temperature of the patient, 103° F. The bath was given at 9 P.M., and, the condition of the patient being alarming, I remained all night an anxious watcher at her bedside. My concern may be better imagined than described. I had, with many mental misgivings, urged a procedure which, until then, I believe I may say, was unknown in the community, and severe condemnation certainly awaited its failure. During the night some encouraging symptoms appeared. She was bathed twice the next day, each time with some slight benefit, but it was not until a somewhat more prolonged bath was given, on the following morning, that the rusty-colored sputa began to come away in any quantity. Four baths in all were given. As showing the condition of the patient and the value of baths, I may relate that her husband, an unusually well-posted clergyman, had cabled the patient's sister in London the news of her impending death. The patient has fully recovered, a result which I think would scarcely have been possible without the baths. One interesting feature of this case is the comparatively low range of the temperature. It never went above 103.5° F. The fever was not entirely controlled by the baths, as it went to as high a point after we had discontinued them as before; but their effect in loosening the exudation and stimulating expectoration and the heart's action was so marked as to be beyond question.

The second instance in which the baths were employed was in the case of W. K——, aged twenty-three, seen with Dr. Walter Ryan, in the fifth day of the disease. The temperature was nearly 105° F.; respirations, 64; and pulse, 144. While on a drunken spree he had been stricken with a severe type of the disease, and had been treated with antipyretics and stimulants *secundum artem* by Dr. Ryan. It was our opinion that death was inevitable in a few hours, but, influenced by the brilliant success in my first case, it was decided to give him the benefit of the baths. They failed to rescue him, but not only did they do no harm, but, we believe, sustained life thirty hours longer than would have been possible without them.

The next case to which I successfully applied the treatment by baths was Willie G——, aged ten. On the third day of an attack of measles he developed pneumonia, and it was only then that I was called to attend him. I found his respirations 84 per minute, pulse above 160, blueness of the lips, and temperature 104.8° F. I lost no time, after informing the family of the gravity of the case, in preparing to give him a bath. In default of a regular bath-tub, and as I deemed an immediate bath imperative, we made use of a large-sized wash-tub in which the boy seated himself, while myself and assistants poured the water over him. He came out of the tub improved. Six hours later, finding alarming symptoms again present, I put him in a second bath. This completed the good effects of the first and started him on the highway to recovery. Eighteen hours after the first bath his respirations were 40; pulse, 126; and temperature, 102° F. Rapid convalescence followed.

The fourth case is that of Mr. W. S——, aged twenty-five, whom I was called to see at a coal-mining station ten miles from the city. Finding pneumonia of the right lung imminent, he was brought to the city by special train and placed in St. John's Hospital, where he soon developed the disease in its most severe type. The temperature reached the unusual figure of 106.2° F., and this despite the employment of antipyretics and the ice-coil. When it reached the highest point the unconscious patient was placed in a bath at a temperature of 95° F., where he was kept for ten minutes. This procedure was repeated in four hours. These two baths were sufficient to break the force of the disease, and steady and rapid improvement was noted from the time of their use. Expectoration, which had ceased with the appearance of the bad symptoms, became again abundant, consciousness was regained, and the heart's action improved. This patient weighed two hundred and eighteen pounds, but the labor of handling him was much less than was anticipated. The small number of baths required was the more remarkable because of his development of adipose.

The fifth case is that of M. J——, aged seven, whom I saw early in the disease, when there was probably little more than congestion present. The symptoms of pain in the side, distressing cough, and elevation of temperature and pulse were great enough to call for active treatment. Instead of giving the usual antipyretics I gave two tepid baths, and was thus enabled to change this picture to one of quietude and freedom from pain, and a rapid convalescence.

The sixth case was that of L. D——, aged sixty-nine, in which, unfortunately, the bath treatment was not given until after severe symptoms of heart-failure had developed. The effect of the bath was good for the time being, and although the patient did not recover, the bath had nothing whatever to do with the fatal result, which was due to heart-failure. My only regret is that the treatment was not instituted earlier in the case.

The results of my trial of this treatment, it will be seen, give a mortality rate of thirty-three per cent. This is not a very encouraging argument in its favor, but statistics in so small a number of cases should not be used in that way. As a result of my clinical study of the use of baths, I am prepared to indorse the statement of their good effects made by gentlemen high in authority and with a large experience in their employment. My two patients who died were already *in extremis*, and two of the cases of recovery were calculated to give as severe a test of the treatment as one is likely to encounter. The treatment means work on the part of the medical attendant, and he who prefers to write a prescription to using some physical exertion had better remain an advocate of antipyretic medication.

The conclusions I make in closing this very imperfect presentation of the benefits of baths in pneumonia are: 1. They should only be given in those cases which are not progressing favorably. 2. In severe cases nothing is calculated to give so much relief to all bad symptoms. They shorten the duration of the disease and of convalescence, and reduce the mortality. Liebermeister says it has been reduced in his hands from twenty-five to ten per cent. 3. Rules for selecting cases and administering baths cannot be rigidly given. The thermometer is not always the guide for their administration. Difficulty of respiration and lack of secretion should lead to their employment, regardless of the height of the mercury. 4. The temperature of the bath should be one hundred degrees or less, depending on the severity of the case and the condition of the patient. Baths of extremely low temperature I have not found necessary as yet, but should not hesitate to employ them if occasion should require. 5. Stimulants should be given just before entering and on coming out of the bath-tub. The patient should not exert himself in the least. 6. The physician should himself superintend and aid in giving the bath. This rule could only be broken by having trained nurses who are competent to meet the emergencies which might arise.

## RECENT MEDICO-LEGAL CASES.

By HENRY H. RILEY, Esq.,

NEW YORK.

Some little time before this paragraph will be read, the city of New York will have witnessed the unusual circumstance of the execution at one time by hanging of four murderers.

These executions will take place after the long delays and appeals permitted by the law of the State, so that most persons have forgotten the crimes for which they will suffer the extreme penalty of the law. Should there be any bungling in the performance of the sad duty devolving upon the sheriff of the county, a new interest will be given to the Electrical Execution law, which some people are so earnestly trying to have set aside on the grounds that it permits a "cruel and unusual punishment," forbidden by the constitution of the State.

It is difficult to see, however, why electricity should be more cruel in its working than hanging, as sometimes carried through. In a double execution occurring only a few weeks since at Louisville, the papers give the following horrible account of the mode of death: "Smart turned round and probably died instantly, but Dilger slipped the noose, the rope catching him over the chin at the lower teeth. He was seemingly unhurt, and was drawn up by the rope until his shoulders came through the trap, when the deputies took him by the arms and pulled him upon the scaffold. A new rope was brought into service, and when the noose was adjusted Dilger asked, 'What's the matter?' When he was told he said, 'This shows I should not die.' He placed himself upon the trap the second time by making two hops. The drop was again sprung at 6.39; he was strangled to death."

Considering the fact that there are so many hangings where the condemned persons are slowly and painfully strangled to death, their necks not being broken by the fall, it is very difficult to see how the advocates of this mode of execution in place of electricity have much of an advantage. It is true that no one can tell absolutely how electricity will work until it has been tried, and the trial, to give reliable information, must be upon a human being. As to the probabilities of its action experts differ greatly, as already shown in the testimony given before the referee in the Kemmler case; but there seems to be no uncertainty about the opinion of the greatest electrician of the age, Edison. His testimony was as follows:

"Can an electric current be applied by artificial means, in such a manner as to produce death in every case?"

"Yes."

"Instantly?"

"Yes."

"Painlessly?"

"Yes."

We have little fear that the murderer Kemmler will escape through any sentimental fear that electricity will not do its work, but the condition of the law in New York State is such that, if the court should decide that the use of electricity would be a "cruel and unusual" mode of punishment, he cannot be punished at all.

The knowledge of this probably makes his eloquent counsel the more active in his efforts to have electrical executions abandoned.

In North Carolina an action was recently brought against the city of Asheville because of its neglect in furnishing proper shelter for persons confined in its jails, but the court held there was no liability. It seemed that proper fires and bedclothing were not furnished the prisoners during the winter weather, and the decision was that the city was not liable if it had furnished the supplies required by law. It seemed to be the inference that the jailers might be personally responsible for the neglect in caring for the prisoners.

The court said: "We may safely say that neither cities nor towns can be required, as a general rule, to answer in damages for injuries to prisoners caused by the neglect of their respective jailers, policemen, or guards who may have immediate charge and custody of them, and of which the governing officials of the corporation had no notice. We think that where window-glass in the window of a police prison has been broken, and the bedclothing furnished for its inmates has been destroyed, but the governing officers of the town are not shown to have had actual notice of the breaking or destruction, or to have been negligent in omitting to provide for such oversight of the prison, as would naturally be expected to give them timely information of its condition, there is not such a failure in discharging the duties of construction or superintendence as to subject the corporation to liability."

The State of Massachusetts has a strict law in regard to Sabbath observance, and the courts construe it rigidly. In a recent instance it would seem that a person sold cigars, and the question was whether these could be brought under the designation of "drugs and medicines," which the law permits in Massachusetts, as elsewhere, to be sold on Sunday. The court listened patiently to the argument, and then, in a long and convincing opinion, pronounced the dictum that cigars were not medicines, and that, therefore, the sale was unlawful on Sunday.

The Supreme Court of Montana has just decided that the railroads cannot be compelled to pay for animals killed by their trains, unless they are negligent, and in absence of a law requiring the companies to fence the tracks, and a law to this effect has been declared unconstitutional. The court holds that such legislation is on the line of that attempted in Illinois, where a law was declared unconstitutional which compelled railroads to pay the burial expenses of all persons dying on, or killed by, their trains. In this instance the court said that death might be caused absolutely without any fault or negligence of the company, and it was unjust to put a liability where such was the case.

The California Supreme Court has declared that cities in that State are not liable for persons injured by falling into open sewers kept insufficiently guarded, where the liability for such injuries is not expressly stated by statute. One of the judges, who dissented from this opinion, said that, if the law required the municipal authorities to keep the streets in safe condition, this carried with it a liability for injuries, even though no express provision was made by the law for compensation. The latter view is probably the prevailing one in most of the States.

The Georgia Supreme Court holds that it is within the discretion of the trial court to require the plaintiff, suing for a physical injury alleged to be permanent, to submit to an examination by competent physicians to ascertain the nature, extent, and probable duration of the injury, so as to afford means of proving the same at the trial.

The judge cited with approbation the statement in "Thompson's Trials," as follows: "In modern trials of civil actions for physical injuries, the question has frequently arisen whether the court has power to order an inspection of the body of the plaintiff or person injured, for the purpose of ascertaining the nature and extent of the injuries. Some of the courts, carrying in their minds no higher conception of a judicial trial than the conception of a combat in which each of the gladiators is permitted, within certain limits, to deceive and trick the antagonist and the umpire, have decided the right of the defendant to have an order for such inspection.

"Other courts, taking the more enlightened view that the object of a judicial trial is to enable the State to establish and enforce justice between party and party, have held that it is within the power of the trial-court, in the exercise of a sound discretion in proper cases, upon an application seasonably made, under proper safeguards designed to preserve the rights of both parties, to order such an inspection, and to compel the plaintiff or injured person to submit to it.

"Another court has held that where a plaintiff in such an action alleges that his injuries are of a permanent character, the defendant is entitled, as a matter of right,

to have the opinion of a surgeon based upon a personal examination, unless there is already an abundance of expert evidence; in which case the court, in its discretion, may refuse to order an examination. Another court has ruled that the trial-court may require the plaintiff in such an action to submit to a medical examination, and dismiss his action if he refuses to comply with the order.

"This conclusion may be placed upon the higher ground that, when a person appeals to the sovereign for justice he impliedly consents to the doing of justice to the other party, and impliedly agrees in advance to make any disclosure which is necessary to be made in order that justice may be done." It will readily occur to the reader that the main ground of objection to the rule would be the danger to which delicate and modest females might be exposed, and in regard to this the judges say: "There would be no danger, we think, in this country, of an examination being ordered needlessly, or where an improper shock to modesty or feelings of delicacy would be likely. We decide simply that the power exists, and that in each case it is to be exercised or not according to the sound discretion of the presiding judge."

## Clinical Department.

### ARTIFICIAL ANÆSTHESIA DURING SLEEP.

By THEODORE POTTER, A.M., M.D.,
INDIANAPOLIS.

I WAS called at 9 P.M. on July 2d to see a case of injury to the arm. The patient was a boy, aged eight, rather delicate in appearance, timid, and of slight build, but whose general health is good. The injury had occurred nearly two hours previously, and the swelling and extreme pain prevented a thorough examination without an anæsthetic, which being given, fracture of the lower end of the humerus was found, the internal epicondyle being broken off.

Seven weeks before this the boy had received a severe scalp-wound, during the suturing of which chloroform was given. This was a short time after a meal; he vomited freely during and after the use of the anæsthetic, and was sick for some hours. He was therefore now much frightened over, and dreaded, the idea of having to take "that nasty stuff again."

Adjusting the arm in a comfortable position I left him for about half an hour. When I returned with Dr. J. W. Marsee, of this city, he was sound asleep.

At the solicitation of his family I made the attempt of giving the anæsthetic without waking him. The experiperiment was completely successful. The patient passed directly from sleep into the artificial anæsthesia, the only signs of irritation being a slight holding of the breath, and a few side-to-side movements of the head just before complete anæsthesia was reached.

The dressing lasted twenty minutes; the anæsthetic was then withdrawn, the patient passing into natural, quiet sleep, without the slightest sign of disturbance. He did not vomit during or after the chloroform, and experienced no perceptible ill effects from it. Three and one-half hours afterward, at 2 A.M., he awoke, not having any knowledge of what had occurred, and expressed surprise that his arm had been dressed.

The anæsthetic used was chloroform. It was given on a small, thin handkerchief, gradually at first, and with very free admixture of air, near an open window, and was as gradually withdrawn. The quantity used was exactly three and one-half drachms. The supervention of complete anæsthesia was quite sharply marked by the change to regular, deep, easy breathing, and full relaxation following slight rigidity of the muscles of the face and chest.

A plaster dressing was applied, completely immobilizing the arm; there was thus the least possible irritation remaining after the withdrawal of the chloroform.

Though the production of artificial anæsthesia during sleep is certainly a nice thing, if it can be successfully carried out under such circumstances, the question is of interest chiefly from a medico-legal stand-point.

The subject being under discussion in the local medical society a few years ago, it was tested a number of times by Dr. W. N. Wishard, then Superintendent of the Indianapolis City Hospital, the subjects being adults. In every instance it failed; and failure has been the result in the large majority of instances in which it has been tried. How rarely, then, must it be successful in the hands of excited, bungling, incompetent persons who attempt it for criminal purposes?

A considerable number of successful cases is, however, now on record; and it is generally agreed that it is more likely to succeed with children than with adults. The two cases reported by Dr. Cluness [1] were in children. Dolbeau, in his report on the "Employment of Chloroform in Relation to the Perpetration of Crime," [2] concludes that children are less difficult to manage than adults. Wood [3] makes the same statement.

In all the cases which the writer has been able to find, chloroform was the agent used.

The subject is well summarized in Lyman's work on "Artificial Anæsthesia and Anæsthetics." [4] In none of the cases related in this volume, nor in those which I have been able to collect from other sources, with possibly one exception, is it clearly stated whether or not the patient continued to sleep after the chloroform was stopped. In many it is stated or intimated that this condition did not follow. Moreover, it is to be noted that in many of the reported cases (all of those of Dolbeau) the subjects were not suffering from any special irritation, such as an injury, which would probably render the experiment more difficult.

The evidence in most of the supposed cases of the criminal use of chloroform, such as occasionally come before the courts, or more frequently float through the newspapers, is so incomplete or doubtful as to be of little value. This case, therefore, seems of interest as one in which not only was artificial anæsthesia produced during sleep, but was followed uninterruptedly by sleep lasting a number of hours, and this in a person suffering from a painful injury.

### A CASE OF FECAL FISTULA—OPERATION—RECOVERY.

By H. W. BOONE, M.D.,
SURGEON TO ST. LUKE'S HOSPITAL, SHANGHAI, CHINA; PRESIDENT OF THE MEDICAL MISSIONARY ASSOCIATION OF CHINA.

THIS patient comes in with the following history, furnished by the doctor who first saw the case, November 1, 1888: "Nineteen days ago was seized with pain in inguinal region, which he said soon became general over the whole abdomen. After his seizure there was for some days more or less stercoraceous vomiting. On the sixteenth day he says an oblong tumor, which had been observed in the inguinal region, ulcerated through, and discharged much fæces, pus, and fluid. After he was seen an enema was given, which resulted in the passage of a moderate amount of very firm fæces. Some days after this the bowels began to act spontaneously but irregularly. For two months past he has passed one-half of his fæces by anus, and one-half through the opening in inguinal region."

Admitted to St. Luke's Hospital, March 23, 1889, a healthy-looking, fairly well-nourished lad of nineteen. He has a small opening over the region of the cæcum, from which fairly well-formed fæces are passed. There are the marks of two sinuses, one running toward the scrotum and one toward the median line, which are fully healed up. The opening of the fistula is too small to admit of the passage of the little finger, and there appears to be a

cavity between the skin and bowel which seems at times to fill up, and then, after a free evacuation, to become smaller. A probe, slightly curved, passes freely upward and appears to be in a large cavity; it can also be passed directly downward for two inches, but not in any other direction. The patient was carefully prepared for the operation by bathing, the evacuation of the bowels, appropriate food, and the cleansing and disinfection of the parts. On March 27th, at 10.45 A.M., chloroform was administered by Dr. Reid, and with the kind assistance of Drs. Jamieson and Deas, and Surgeon Kellard of H.M.S. Mutine, I proceeded to operate. A free incision was made over the site of the lesion, and the parts were dissected up, thus opening into a cavity which connected with the cæcum. A ragged irregular wound was found two inches above the lower end of the cæcum, nearly transverse in direction, and one and three-quarters inch in length; the mucous membrane was ragged and everted. On insertion the finger passed up readily in the direction of the ascending colon, also downward for nearly two inches. With one finger in the gut, I then carefully freed the bowel in this vicinity from some cicatricial attachments, removed some shreds of areolar tissue, and then thoroughly cleansed the parts with sponges wrung out of a warm two per cent. solution of carbolic acid. I then put in a double row of "Lembert sutures" of fine silk, and closed the opening, passing two stitches at either end of the line through healthy tissues beyond the angles of the wound. The edges of the wound having been thus inverted, and being in close apposition, the parts were cleansed, a short india-rubber drain-tube was inserted beneath the skin, and the wound of incision was united with interrupted sutures of catgut. Borated cotton was applied over the line of incision, then Gamgee pads; a wide bandage was applied round the body, with a spica in the groin. The patient bore the operation well. He was put to bed and allowed nothing but one teaspoonful of weak hot tea from time to time. On the evening of the day of the operation his temperature was 99.3° F.; on the next evening it was normal, and continued so afterward. Slight chloroform nausea for twenty-four hours. At twenty-five hours after the operation, began the injection of beef-juice per rectum. After one day he objected so strongly to the use of enemata, and to taking Valentine's meat-juice by the mouth, that I ordered three ounces of equal parts of milk and rice-water to be given him, in spoonful doses, during the day. Fourth day: Slight stain on dressings, which were removed; they were stained with pink serum, wound quite healthy, no pain or tenderness; fresh dressing applied; rice-water and milk, eight ounces. Sixth day: Enema, followed by a small passage containing fæces; meat broth in addition to milk and rice. Eighth day: Change dressings; wound healed except track of drain-tube, which was removed. Ninth day: Minced meat and boiled fish with the rice and milk. One-half ounce of salts in morning was followed by two natural stools in the afternoon. Eleventh day: Two natural motions without the use of any aperient. After this time a regular and natural stool every day. On the morning of the thirteenth day removed the third dressing. Wound entirely healed; a small pad of absorbent cotton and a bandage were applied to keep his fingers from the groin. On the seventeenth day allowed him to get out of bed and sit in an arm-chair. April 20th: Returned to his ordinary native diet, and walked about the hospital yard. April 22d, twenty-six days after the operation, he is perfectly well, and is discharged at his own request.

*Remarks.*—This young man had twice attempted suicide, and there is no doubt that his parents, with true oriental disregard for the sanctity of human life, were quite willing to allow him to make away with himself. His complete recovery seemed to them but little short of a miracle. The man came to me in very good condition, for his physician had kept the parts cleansed, healed up the sinuses which had burrowed in the surrounding region, and had put the parts into a healthy condition; while by careful attention to the general health of the patient he had put him in a good way to recover from the results of an operation.

This is an example of a case where the operation was an easy one, and there were no untoward complications. My former cases were of fistulæ, in which the small intestine was involved, and where the two ends of the gut connected with the artificial anus were resected and the cut ends joined together by sutures, a much more dangerous operation for the patient.

This case is reported as showing that it is not every case of fecal fistula in which the operation for cure is specially dangerous; and that, while the modern plan of cutting down and operating directly upon the injured portion of bowel is the best, in a certain proportion of cases it is not attended with very great danger to the life of the patient.

In this case the fecal fistula seems to have resulted from some obstruction of the bowel, for we learn that he had severe pain in the inguinal region, and after a few days vomiting of stercoraceous matters. A fecal abscess was then formed, which later on effected an opening through the integument. There was ulceration of the cæcum, but nothing to show whether the appendix was or was not involved in the inflammatory process. As the appendix was completely shut off from the site of the injury, it was deemed best to confine attention to the local lesion and not to go exploring for undiscovered troubles. The bowel opened indirectly to the surface; the skin-wound was quite small, and the fistulous track was irregular; there was a cavity containing pus and fæces between the wall of the abdomen and the bowel; it is a variety known as the sterco-purulent fistula. The method employed—of putting in a double row of Lembert sutures, and of inserting a couple of stitches beyond each angle of the wound—seems to me the one which offers the greatest safety. Two rows of stitches give greater security from yielding or leakage than one; the extra stitches at the corners of the wound made sure that no openings were left at those points. The very fine silk used would seem to be the most reliable material for the sutures.

The wound never gave any trouble at all, and in less than thirteen days it was entirely healed up. With our modern style of operating and dressing, this is the result which we have a right to look for. Since giving up the use of the spray, and then the general use of the irrigator in all cases, I find more and more that perfect cleanliness and dry dressings give me the best results, and that operations for laparotomy, the radical cure of hernia (so called), and other operations go on to a cure with but little if any untoward complications.

## CASE OF IMPERFORATE ANUS.

By WILLIAM PERRIN NICOLSON, M.D.,

ATLANTA, GA.

On the morning of the 31st of July, 1889, I was called hurriedly to see the child of Mr. Henry Denham, farmer, with the statement that the child could not have an action from the bowels on account of the absence of the anus. Upon arrival I elicited the following history of the case: The child was born on the 29th of July, and was delivered by a midwife in the neighborhood. According to the usual custom a dose of castor-oil was administered, and as this had no effect the dose was repeated during the day. Failing the next morning to secure an action, a third dose was administered. At this point a physician was called in and made an examination, with the result of detecting the true nature of the trouble. I was called, and saw the child about noon of the second day, and about forty-eight hours after birth. There were evidences of distress in the face, and I was told that he had been crying in great agony for some time before.

Upon examination the anus appeared normal, but when the buttocks were separated there was revealed a complete closure. There was even the appearance of a small ex-

ternal pile near the margin of the anus. The crying of the child upon my efforts of examination caused the distended rectum to bulge out, showing that the gut was not far away.

The patient being held in the lap of the assistant, an incision was made from the tip of the coccyx across the anus, and soon after passing through the skin there was a gush of gas, and then such a stream of meconium as passed away I should never have believed possible in so small a child. It continued for more than ten minutes to ooze away in a constant, though somewhat intermitting stream. Finally the opening was made large enough to let my little finger pass into the rectum, and the patient was left with instructions to the nurse to introduce the finger twice daily for some time. I have since learned that he is doing well. Cases of imperforate anus are sufficiently rare to give them considerable interest, and this belongs to the rarest class.

## Progress of Medical Science.

Mechanical Treatment of Gleet and Sexual Asthenia.—Dr. Szadek, of Kïev, has published a paper on the treatment of gleet by the introduction into the urethra of Beniqué's curved tin bougies anointed with either Unna's salve (℞. Olei cacao, 100 grammes; ceræ flavæ, 2.0 to 5.0; argenti nitrici, 1.0; balsami Peruviani, 2.0. M. f. ung.) or Sperling's (℞. Lanolini, 20.0; ceræ albæ, 4.0; argenti nitrici, 0.1 to 0.3. M. f. ung.). In nervous or very sensitive subjects, in whom the insertion of the bougies gives rise to pain and erection, a from three to five per cent. solution of cocaine should be previously injected into the urethra. During the first sitting the bougie is left *in situ* not longer than for three to five minutes, but later on the duration of the *séances* is gradually increased up to fifteen or even twenty minutes. The sittings are repeated every two or three days, except in very inveterate or atonic cases, in which a daily introduction of the instrument is advisable. As to the size of the latter, the author uses a set from No. 18 to No. 30 Charrière, commencing with the least irritating bougies and gradually ascending to even larger ones. In relatively recent and mild cases he usually employs Nos. 20, 21, and 22, while in more severe and more protracted ones (which, by the way, constitute a vast majority) he, following Professor Otis, passes by degrees to No. 28, or even No. 30. In patients with narrowed meatus, he enlarges the latter by means of a bistoury or scissors. In such cases, where the lesions are situated in the posterior division of the urethra, Dr. Szadek introduces his bougies even as far backward as the bladder. According to his experience, the deep insertion, when practised with due caution and carefulness, never causes any untoward accessary effects (such as vesical or urethral irritation, etc.). In all, 30 cases of neglected gleet were treated after the mechanical method. In 3 of them, referring to unusually severe or old morbid changes about the urethra, complicated with obstinate vesical affection, the results were far from being satisfactory; but in the remaining 27 the treatment proved highly successful. In 18 of the 27 complete cure ensued (and that in 11 from the bougies alone, and in 7 from the bougies and astringent means). In 9 a considerable improvement was obtained; in fact, the only symptom left was a scanty mucoid discharge recurring from time to time. In relatively recent or mild cases, from four to six sittings proved to be sufficient for effecting a cure. In a majority of cases, however, a one to two months' course was necessary for the purpose, while in some unusually severe cases, where a relapse took place, another similar course was to be repeated some months later. The same method (in the shape of the insertion of Nos. 20 to 25) gave also most gratifying results in eight cases of sexual asthenia with spermatorrhœa and (incomplete) sexual impotence. Dr. Szadek arrives at the following general conclusions: 1. The method under consideration proves very useful (*a*) in many cases of neurasthenic irritation of the urethral mucous membrane; (*b*) in many cases of inveterate gleet, especially in those characterized by infiltration and other morbid changes in the mucous membrane and submucous tissues. 2. It proves beneficial, further, in inveterate gleet of an atonic origin, or in that kept up by local nervous disturbances. 3. In some cases, however, the mechanical treatment must be supplemented by a subsequent course of local astringent remedies. 4. The method is free from any untoward accessary effects, provided it is practised with due precautions (including antiseptics).—*The Provincial Medical Journal*, June 1, 1889.

Irrigation of the Puerperal Uterus.—Dr. Haynes (*American Journal of Obstetrics*) concludes a discussion of this subject thus: 1. Where intra-uterine irrigation is used in the absence of sepsis, use no sublimate, but plain hot water, or salt and water. 2. If the urine is albuminous and scanty, use no mercury. 3. If the urine is slightly albuminous and copious, or if the patient is profoundly anæmic, do not use more than a pint of a solution of 1 : 8,000. 4. Always use tartaric acid and sublimate tablets or powders; dissolve thoroughly in a small quantity of water and mix carefully with a definite quantity of hot water in a pitcher, from which pour into the irrigator. 5. Always use fountain-syringe, and for the uterus a double tube, so as to insure the return of the solution. If for any reason the fluid fails to run out as fast as it flows in (if not through the reflex tube, by way of the channels at its sides), shut off the flow. The irrigator should not be raised more than three feet. 6. Precede by copious irrigation with hot water to wash out blood, etc., which may form with sublimate adhesive albuminous compounds, which may in time be absorbed. Follow by a quart or two of hot water to insure the evacuation of all the sublimate solution. 7. For the uterus use a solution not stronger than 1 : 8,000, and not more than a quart daily. 8. For the vagina use a solution not stronger than 1 : 4,000, and not more than a quart twice daily. Irrigation used in the above way is, we believe, a practice almost devoid of danger. We have made more than one hundred and seventy-five irrigations with the double tube and fountain syringe, with no untoward results except in two cases an unimportant rise of temperature, and in one a severe but harmless chill, and even these slight accidents we feel certain might have been avoided by greater care. Yet irrigation of the puerperal uterus will always be a procedure requiring great care and judgment, and some skill. Enough has been said to make it evident that our opinion coincides with that of Credé and Fehling, that both vaginal and uterine irrigation are attended with undoubted dangers, and should never be employed in the puerperal state unless to meet definite indications.

Fissures of the Tongue.—These obstinate and painful lesions are said to be speedily cured by applying the following mixture five or six times daily:

℞. Papayotine..... 2 parts.
Glycerin, aquæ.....ää 10 "
M.

Posture in the Treatment of Tympanites.—Mr. Oxley, writing to *The Lancet* concerning a case of obstinate tympanites which had resisted all drug treatment, says that instant relief was obtained by placing the patient in the knee-elbow position. He advises a trial of this before resorting to puncture of the abdomen.

---

Salol in Scarlet Fever.—Dr. G. J. Holmes, of New Britain, Conn., in a recent *brochure* on scariet fever, speaks very favorably of the action of salol, and states his belief that the persistent and careful administration of salol in proper doses, according to the age and general condition of the patient, will, in many cases, reduce the temperature, eliminate the poison, and cut short the disease.

## A POSSIBLE CAUSE OF POST-PARTUM SHOCK.

THE subject of sudden collapse of the mother, shortly after labor has come to an apparently successful end, is one of so great difficulty and importance that any thoughtful suggestion as to its cause or cure is welcomed by the practitioner. In the Edinburgh *Medical Journal*, July, 1889, Dr. Ferguson, of Edinburgh, relates three cases—one in his own practice—in which, he thinks, the extreme and sudden prostration which occurred was caused by pressure upon the ovary during the application of Credé's method of expression of the placenta. In the first case the mother, a woman of very nervous temperament, was delivered after an easy, rapid labor, without chloroform or forceps, of her fourth child. As the doctor had not arrived, the nurse, an unusually competent woman, thoroughly acquainted with Credé's method, grasped the uterus and firmly compressed it for half an hour, until the doctor arrived. This kneading of the uterus gave the patient great pain. The uterus contracted well without hemorrhage. Soon after the expulsion of the placenta the mother suddenly became unconscious, with imperceptible pulse, and remained so for three hours. She went through the death-struggles, and looked like a dying person. The pulse then gradually returned, and in half an hour the patient could talk and take stimulants. She recovered without further trouble.

In the second patient, a healthy young primipara, the labor had been normal, except that from rigidity of the external parts inertia threatened and low forceps were used. After waiting a little while for the placenta, the doctor put her half under anæsthesia, and, failing to express by Crede's method, which caused great pain, extracted the placenta by hand. Only a slight hemorrhage occurred. Immediately after the extraction the patient became cold, pale, pulseless, and gasping. She rallied under injections of ether, etc., sank again, and finally returned gradually to a normal condition, passing safely through childbed.

The third case occurred in a healthy young primipara, of nervous temperament. Labor proceeded naturally, but at the end of the second stage a little chloroform was given, and forceps were used on account of fatigue of the patient. After delivery she awoke partially from the anæsthesia, and complained loudly of great pain when the uterus was grasped, begging to be let alone. The pain made her sick and faint, and was worse each time the uterus was compressed, becoming finally unbearable. As the placenta was passing from the vulva the patient became suddenly unconscious, after a period of restlessness and tossing. The uterus was firmly contracted, and there was no hemorrhage from cervix or vulva. There was no perceptible pulse, no breathing, and the patient seemed at the point of death. She remained in this condition three hours, then gradually recovered.

In these three cases there had been no great difficulty in labor, no excessive hemorrhage, no severe operation. Eclampsia and heart disease were easily eliminated. In each there were symptoms of syncope and shock; unconsciousness; feeble, rapid, irregular pulse, sometimes imperceptible at the wrist; dilated pupils; shallow, irregular breathing; cold, clammy sweat; vacant, torpid face, and absolute insensibility to pain. In eight to twelve hours they had completely recovered, feeling only a little exhausted, and having some tenderness of the hypogastrium. The patients after recovery had little or no recollection of what had occurred during the attack. In two of the cases the subsequent progress was normal; in the third there was persistent sleeplessness, leading to a prolonged attack of melancholia, from which, however, the patient recovered.

Dr. Ferguson thinks there can be no doubt that the shock was, in each case, caused by squeezing one or both of the enlarged, tender ovaries between the compressing hand and the hard, contracted uterus. This accounts both for the exquisite pain felt during compression and for the subsequent serious collapse. He supports this view by the observation that, during abdominal section for removal of the ovaries and tubes, if the ovaries are roughly handled or torn before the ligature has been tied, the patient, though anæsthetized, becomes generally affected by shock, exhibiting dilated pupils, coldness of extremities, clammy sweat, fluttering pulse, and irregular, shallow respiration. These symptoms disappear after the ligature is tied.

He goes on to show by quotations, and from personal observation, that in a considerable proportion of cases the uterus, during the third stage and after delivery, lies obliquely in the pelvis, so that the ovaries, which cling closely to its sides, lie the one in front of the transverse line, the other behind it. The fingers which grasp the uterus from behind may, in certain of these cases, very easily squeeze the ovary which lies posteriorly. In our attempts to grasp the uterus, also, we may, unintentionally, twist it on its axis so as to bring the ovary where it may be squeezed. When the patient lies on the left side the hand naturally grasps the uterus in such a way that the thumb in front is a little to the right, and the fingers behind are a little to the left of the median line of the pelvis, and as the uterus is generally rotated to the right it is grasped antero-posteriorly and the ovaries are avoided. When the patient lies on the back this is not the case, the rotated uterus being grasped obliquely and the ovaries endangered. In most cases the compression required is slight, and a woman of strong nerves will bear it, even when the ovary is involved, without inconvenience. But where pain is experienced during compression, or where considerable force is required, the physician should take care to find how the uterus lies before he applies pressure. Lateral compression of the post-partum uterus should never

be used except in cases requiring irrigation of its cavity, when the Fallopian tubes should, if possible, be very gently compressed, in order to prevent regurgitation of the fluid through them into the peritoneal cavity.

Many of the attacks of syncope which occur immediately after the third stage, or during it, and which are ascribed to the very slight hemorrhage which has normally occurred, ought to be put to the account of that energetic and forcible kneading of the uterus and its adherent ovaries which an over-zealous accoucheur thinks necessary ot prevent a more or less visionary post-partum hemorrhage.

---

MEDICAL JOURNALS AND THE NAMES THEY GO BY.

We chronicled not long ago the birth of a medical journal in St. Joseph, Mo., to which its sponsors had given the rather extensive name of *The Western Medical and Surgical Reporter*, and we are pained to learn that the youngster has not met with as cordial a welcome from all its contemporaries as it received from us. The cause of the cold, or we might say hot, reception that it has encountered is to be found in the fact that its title resembles closely that of several existing journals. *The Medical and Surgical Reporter* administers to it a not over-gentle reproof, and *The Western Medical Reporter* has cut short the vacation of its fighting editor, and called him home to sharpen his knife and clean his gun preparatory to a busy season. The Cleveland journal with a similar name has not yet been heard from, but he has been there before, and probably will not care to say anything that will tend to reopen old sores.
